## SUMMARY

### PROCESS FOR THE PRODUCTION OF PETROCHEMICAL BASIC BUILDING BLOCKS 1/

by

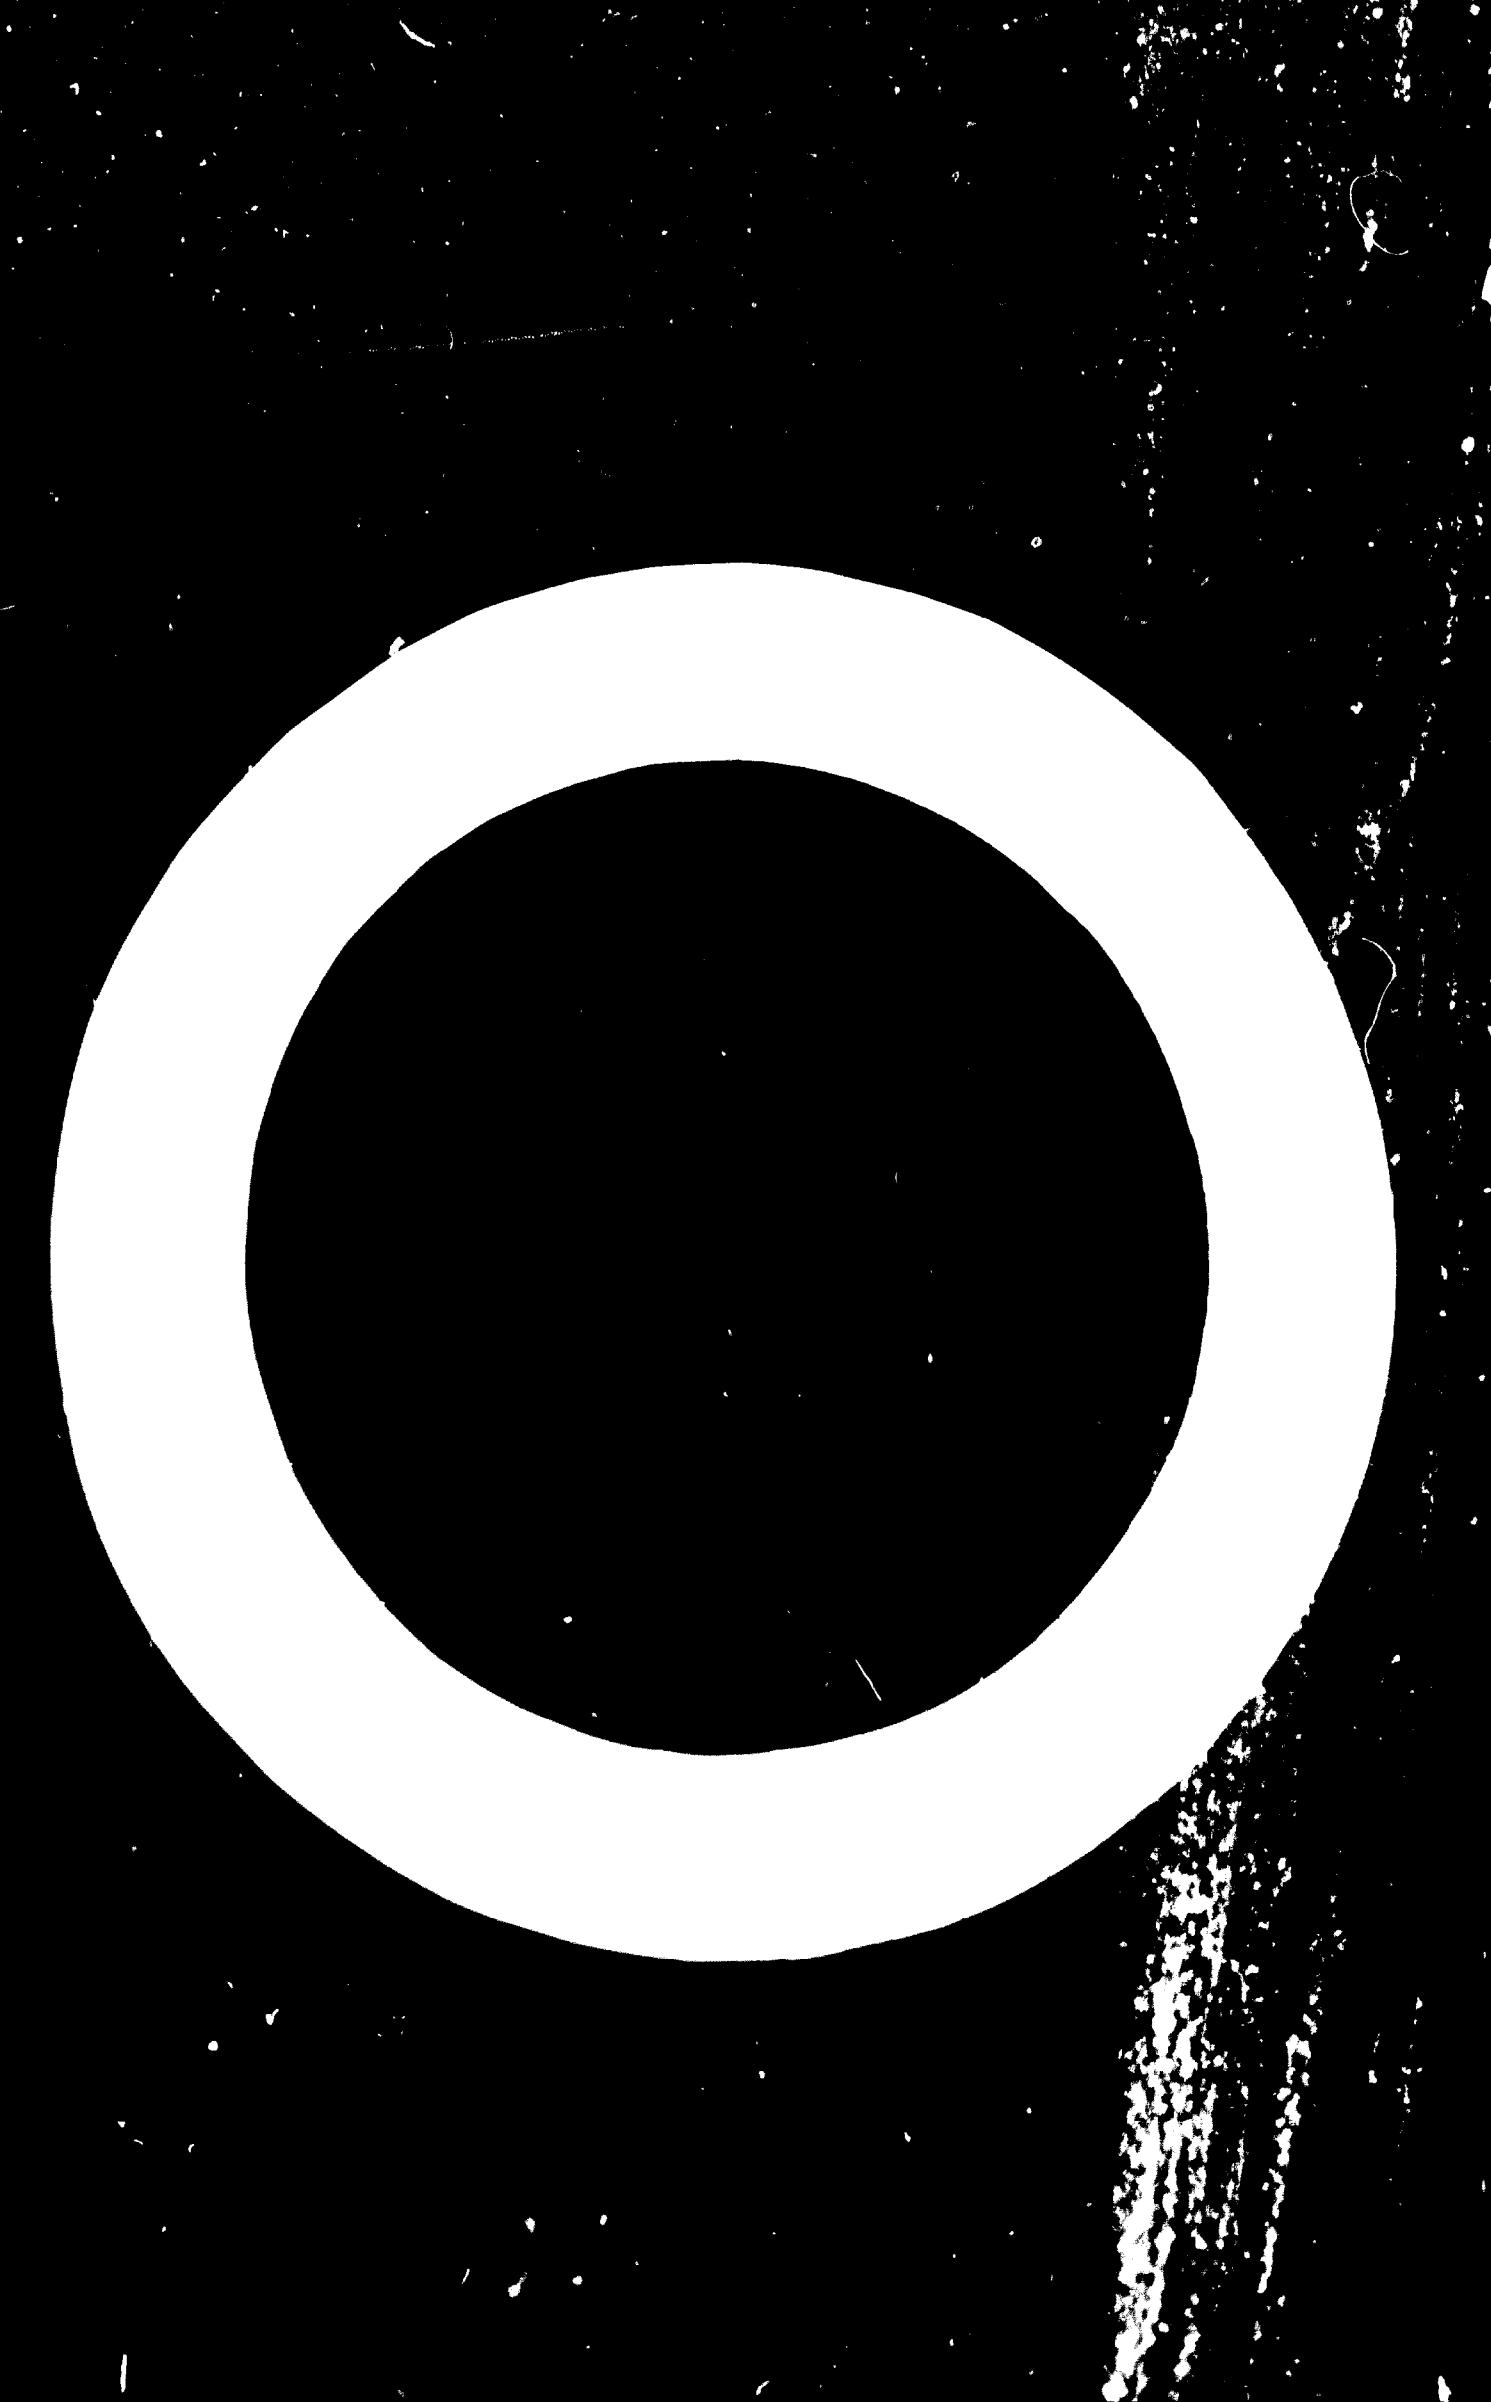

H.V. Kemptner

Hoechst-Zhde International GmbH  
Bad Soden  
Federal Republic of Germany

In this paper the author discusses some of the processes now in operation or being developed which enable petrochemical building blocks to be made from raw materials other than naphtha. Recently developments include the producing of cyclohexane, pentane, heptane, octane, benzene, toluene, m-xylene, ethylbenzene, and styrene.

The present state of the art of these methods will be illustrated. The present difficulties and problems in the development of the processes will be discussed. The advantages of the different processes will be outlined and their disadvantages will be pointed out. The results of a number of industrial scale plants will be presented, and some general conclusions will be drawn.

1/ This paper is based on a presentation given at a symposium on "The Development of the Petrochemical Industries in Developing Countries" organized by the Economic Commission for Europe, Geneva, 23-27 July 1969.

C<sub>4</sub> stream (55% butadiene), and 0.45 tons of pyrolysis naphtha.

- (2) Production of acetylene and ethylene by the submerged flame process. In this process oxygen is, as it were, burnt underneath the surface of the oil, as a result of which cracking of the oil at a very high temperature in the neighbourhood of the flame takes place, the large volume of oil lessing to rapid quenching of the products of cracking and hence retention of a considerable quantity of acetylene. The details of the process and its economics are described. 1 ton of acetylene and 1.18 tons of ethylene are obtained from 1.27 tons of crude oil and 5.1 tons of oxygen.
- (3) Crude oil cracking by the Heechist A7 process. This is at the development stage. The principle lies in the combustion of the tail gas with oxygen followed by the injection of secondary steam and the petroleum fraction to be cracked. The temperature is controlled by the quantity of petroleum injected which itself determines the acetylene - ethylene ratio. The process is fully described including an economic assessment.
- (4) The BIL process for the manufacture of acetylene. The current process is described in which natural gas, liquid gas or naphtha is cracked by the heat developed from the incomplete combustion of the raw material with oxygen.
- (5) The hydrogen electric arc process. This enables a much higher yield of acetylene from hydrocarbon raw material to be obtained. Hydrogen is used as a carrier gas. The techniques of avoiding soot and the burning of electrodes are described.
- (6) Purification and conversion of olefin fractions by hydrogenation. The propylene fraction is only hydrogenated to remove methyl-acetylene and propadiene for the production of polymer grade propylene. Various combinations of these operations are discussed and evaluated. If there is no demand for propylene it can be fully hydrogenated and returned to the cracking plant.

Butadiene is normally removed from the C<sub>4</sub> stream (see section 7).

The residual stream must be hydrogenated to free from the last traces of butadiene. Di- or triisobutene produced in the Bayor oligomerization process can be hydrogenated by the Bayor cold hydrogenation process to very pure isoparaffin.

- (7) The MIP process of BASF using N-methylpyrrolidone with 5 to 10 water to extract butadiene from the C<sub>4</sub> stream is described in full detail with equations.
- (8) Isobutene is sometimes required as a monomer, e.g. for the production of rubber polymers. The BASF process for its recovery via sulphuric acid treatment is described.
- (9) The BASF isoprene extraction process using N-methylpyrrolidone is described. This is still at a development stage.
- (10) The cold hydrogenation refining of a pyrolysis naphtha to free the product from acetylene and diolefines to make it suitable for motor gasoline is described.
- (11) The BASF-Scholven process for the gas phase hydrogenation of pyrolytic naphtha is described. This removes sulphur and olefins and makes it suitable for the extraction of aromatics.
- (12) The extraction of aromatics by N-methyl pyrrolidone from pyrolytic naphtha by the Lurgi-Trisevan process is described in considerable detail and fully evaluated.
- (13) Aromatics can be dealkylated e.g. toluene converted to benzene by the BASF-Scholven process. Toluene and crude hydrogen e.g. from a catalytic reformer are converted catalytically to benzene and methane. Recirculation of unconverted toluene is carried out and about 1.5% diphenyl produced as a by-product.

The raw materials which are suitably used for the production of the petrochemical basic building blocks such as ethylene, acetylene, propylene and the C<sub>4</sub>-olefins, will always be adapted to the given local conditions. These interrelations were decisive for the fact that two large chemical companies in the Federal Republic of Germany, independently of one another, developed processes for the cracking of full range crude oils. Cracking was carried out in the middle temperature region (below 300° C) for the production of the elutriated ethylene, propylene and butylenes. These processes are known as the BASF fluidized bed process and the Hoechst moving pebbles process.

Compared with the USA, the pattern of consumption of petroleum products is completely different in Europe, and especially so in the Federal Republic of Germany. This also has a bearing on the selection of raw materials which are available for the manufacture of petrochemical basic building blocks. In the USA, 61% of the ethylene is made from ethane, 32% from propane and only 7% from cracked petroleum hydrocarbons (condensate, naphtha). In Europe, the situation is quite ascertained nearly exclusively from the thermal cracking of naphtha due to the large-scale production of ethylene as a byproduct of aromatic hydrocarbon block refining. In Federal Republic of Germany, a special position is also taken by acetylene obtained from calcium carbide. This development must be mentioned in order to emphasize that there is a special interest in the development of vinyl chloride for the manufacture of acetylene from petroleum hydrocarbons. To repeat the former, the production and the distribution of vinyl chloride like the refineries independent of raw material requirements, has been a major advantage of crude oil or shale for producing petrochemicals and has added much to the chemical industry during recent years.

The wide experience with electrothermal processes also triggered the development of hydrotreatment cracking using the hydrogen-electrolytic arc technique. Special attention was directed in this country to the development of processes for the recovery of individual fractions of very high purity grade. Technological contributions have also come from our country with regard to separation of the aromatic hydrocarbons previously hydrogenated by polycyclic naphthalene.

In the following, it will be reported on the processes being operated at the Institute of Fuel already, as well as those which are still in developing stages.

#### I. The BASF fluidized-flow process for the production of synthetic gasoline

##### 1. The principle of the process

The production of synthetic gasoline from crude oil is of interest because it is possible to do so regardless of naphthalene.

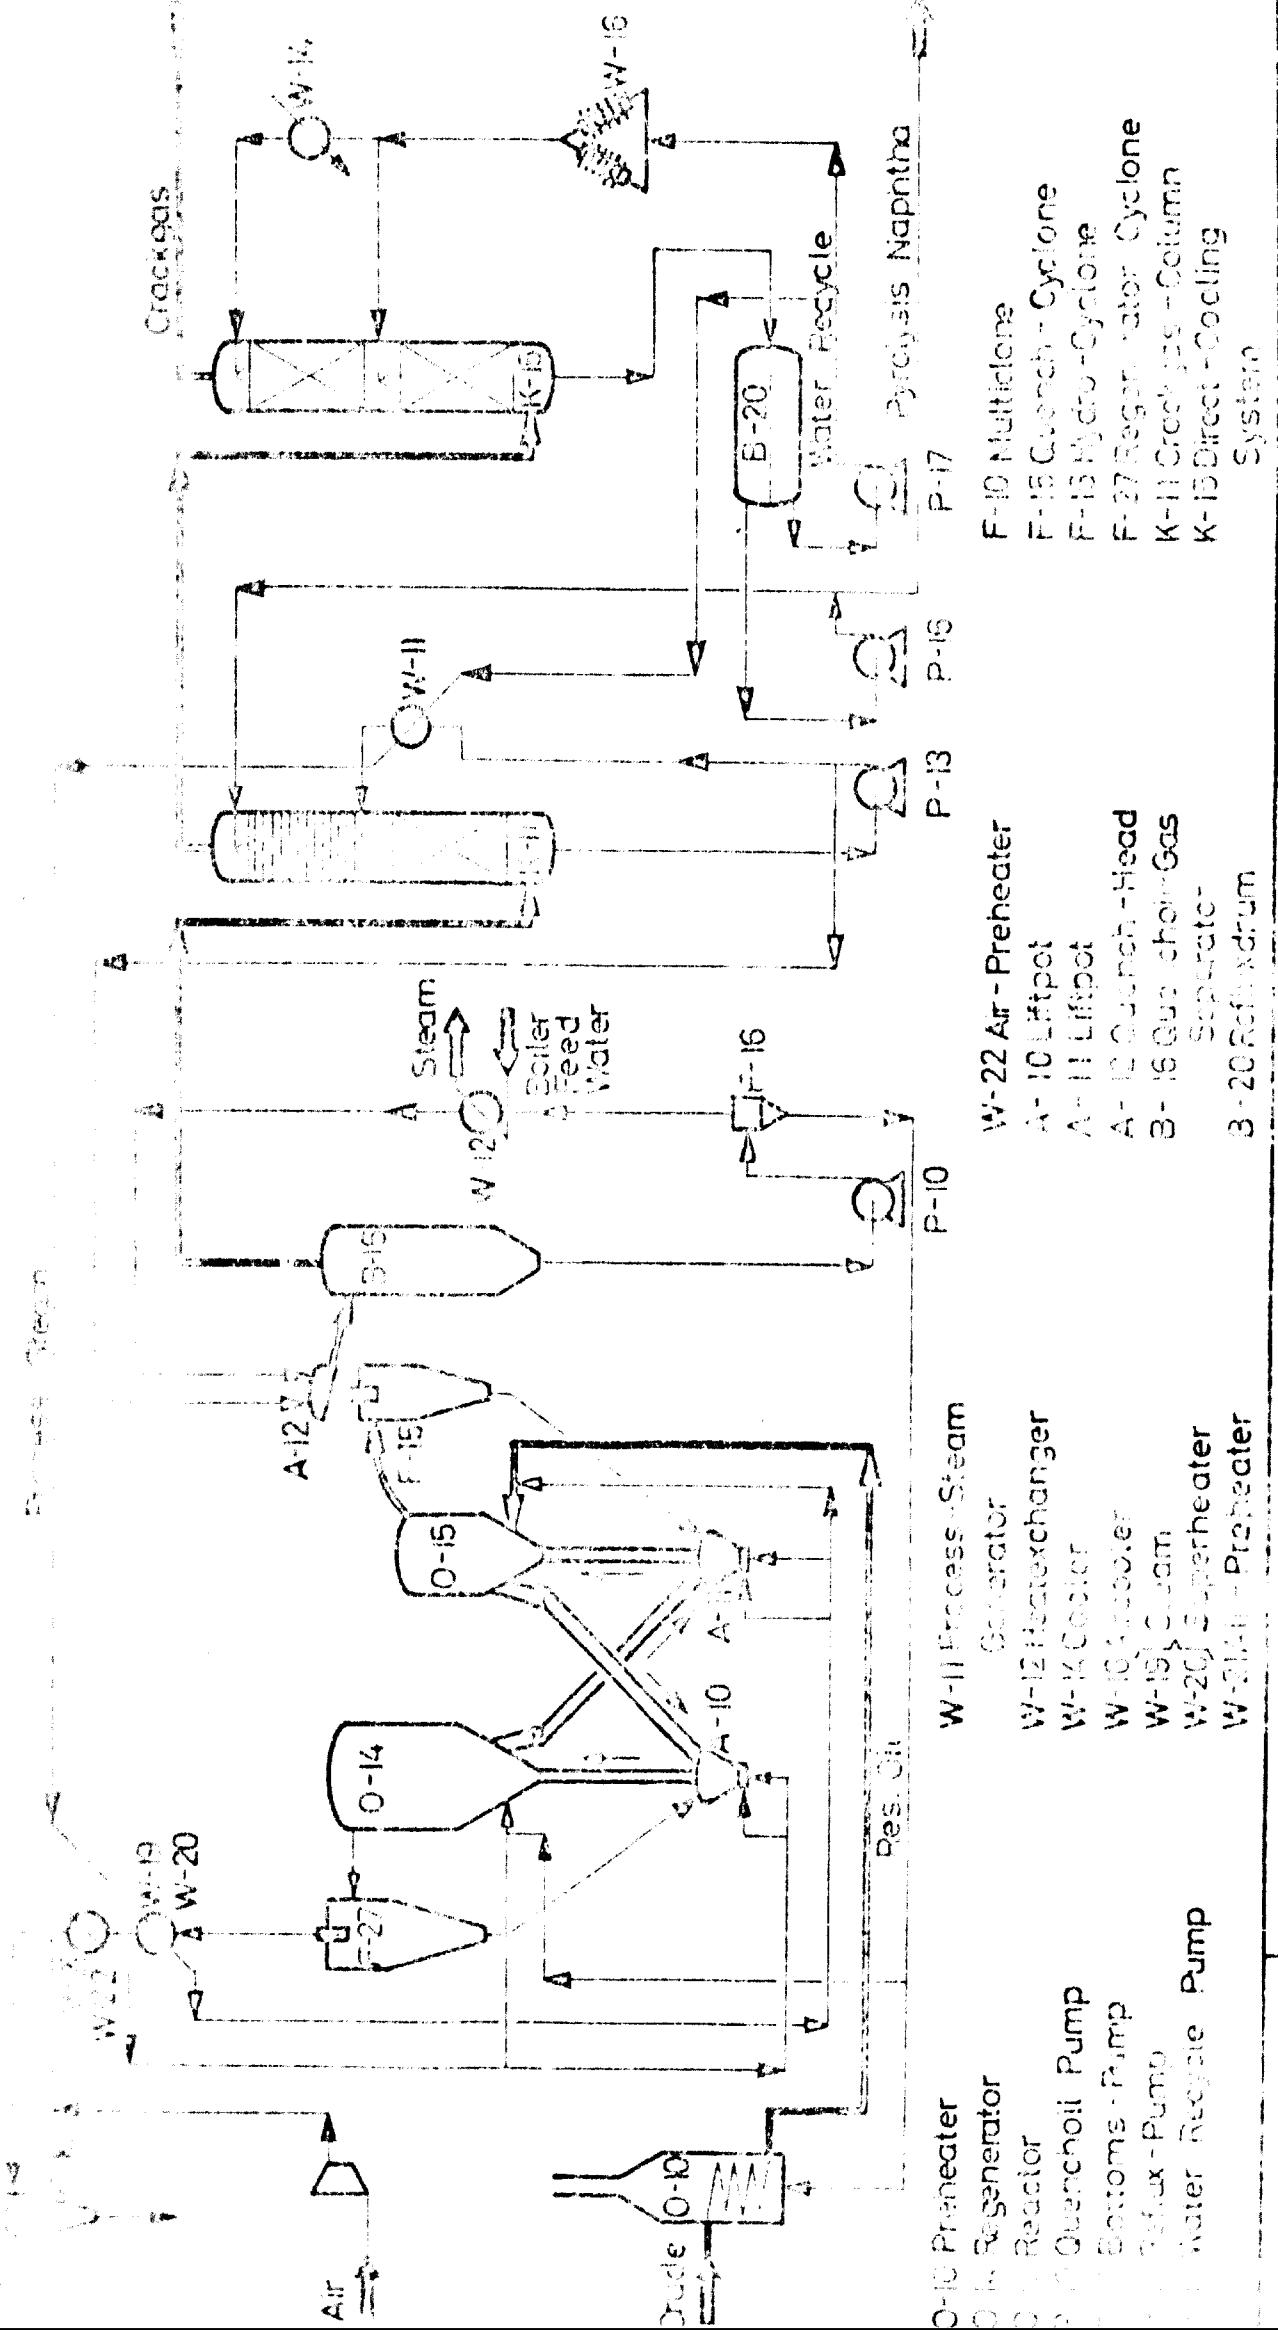

The basal fluidized hydrogenated process requires oxygen for supplying the heat of combustion. The reaction takes place at about 700 °C in a fluidized bed of petroleum coke. Ozone carries to the fluidizing medium to which oxygen is added. The heavy fractions of the reaction products are returned to the fluidized bed and are burnt there together with the coke and the petroleum coke.

The coke may be oxidized with flue gas. This, as well as the need for oxygen in the burning component are a disadvantage of the process.

The fluidized-flow process circumvents these drawbacks by carrying out

Crude - Vacuum - Cracking - Vacuum - Distillation - Process

Fig 1

the generation of heat and the cracking reaction in separate parts of the cracking unit. In this way, air can be used as the combustion agent. The flue gas escapes into the atmosphere which means that cracking separation is avoided. On the other hand it is necessary to circulate large amounts of heat carrier between the reactor and regenerator. This heat transfer is probably the basic difference between this process and the fluidized bed process, and required many years of development work.

An inorganic material, as spherical as possible, is used as the heat carrier. At those warmer operating conditions must be low. A mullite 4% Al<sub>2</sub>O<sub>3</sub> grain size between 0.5 and 2 mm has proved the most suitable material.

The details of operating steps can be taken from Fig. 1. The heat carrier is circulated between the reactor 0-15 and the regenerator C-1a, in the direction indicated by arrows. The amount circulated is controlled by the valve 0-15. At 0-11 and 0-11 the pneumatic conveyor starts up and the 0-11 valve opens. The conveying medium on its regenerator side is directed through reactor side stems. The length of the sloping downpipes is such that indeed short reactor and regenerator are surely separated on the basis of the flow of nitrogen, the two large apparatuses have to be placed at a distance of about 20 m.

In the first trials, fluidized beds with grids were used both for the reactor and the regenerator. However, there were difficulties as regards cleaning and removing of solids; this was best overcome by going away from the grid and using a conical bed. The conical bed resulted in excellent operating conditions and did not entail any loss in yield.

-1-

compared to the fluidized bed with grid. However, it cannot be described as an actual fluidized bed any more. It is a bubble bed with powerful jolt up, and a low initial delivery rate. Initially, coarse solids carried by the preheated crude oil are entrained and carried upwards, together with the entrained steam, through laterally placed ports in the tube. About 60% of the coarse are used per ton of crude oil. Owing to the slight difference in the subsequent separation of the distillate operations at slightly different pressure, the cracking temperature lies between 700 and 730°C. The residence time in the reactor, as in the fluidized bed process, is about 2 seconds.

The heated oil leaves the reactor, passes by way of a heat exchanger, to the incinerator which is used for combustion of the coke which is being produced from the cracked vapors. The coke is collected in a bin and sent to the incinerator. The incinerator is heated by the cracked vapors, and the heat is used to heat the oil which is sent to the reactor.

In the reactor, due to incomplete separation, a proportion of the catalyst fine powder will be entrained in the fluidized bed. A quenching cyclone is provided in the reactor vessel in order to remove the entrained proportion of the catalyst. The catalyst is collected and sent by an elevator to the plant application of ceramic pebbles. The volatile fines are filtered and sent to the incinerator to burn away the remaining carbonaceous material. Since the oil leaving the reactor is carrying secondary volatiles, for this reason, about 5% of the cracked light vapors are diverted into the quenching cyclone. They are recycled from there to the volatile circulation. There is no risk of erosion here since it is passing over SiC-bricks.

1. The cracking stage consists of two stages, the first stage is  
the vapor phase stage of the hydrocracker unit.

2. The second stage is the liquid phase stage of the hydrocracker unit.

3. The hydrocracker unit is a packed column operating under a pressure of 100 psig.

4. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

5. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

6. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

7. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

8. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

9. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

10. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

11. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

12. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

13. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

14. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

15. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

16. The hydrocracker unit has a total capacity of 1000 bbls per hour of feed.

of ethylene produced. The following yields of by-products are obtained:

C <sub>3</sub> -cut (65 % propylene)	0.50 ton/ton C <sub>2</sub> H <sub>4</sub>
C <sub>4</sub> -cut (65 % butadiene)	0.25 " "
Pyrolytic naphtha	0.45 " "

The residual oil formed is burnt quantitatively in the process, whilst an excess of 0.7 ton/ton C<sub>2</sub>H<sub>4</sub> of fuel gas (H<sub>2</sub> + CH<sub>4</sub>) remains.

If

the C<sub>3</sub>-cut is valued at DM 165/m.t. (4 DM = 1 US \$)

the C<sub>4</sub>-cut at DM 105/m.t.

pyrolytic naphtha at DM 30/m.t.

and the fuel gas at DM 30/m.t.

assuming a selling price of DM 1.21/kg C<sub>2</sub>H<sub>4</sub> (2.4 US Centa/lb) is arrived at a total annual cost of DM 1,000,000,000.00. In addition the investment costs of DM 170,000,000  
for plant, piping, fittings, electrical, depreciation, taxes, interest and maintenance.

## 2. Preparation of Acetylene and Ethylene by the BASF

Process for the Preparation of Acetylene and Ethylene

The apparatus consists of a vertical glass tube 10 cm. long, closed at the top.

The tube is connected to a gas inlet tube which is inserted into a horizontal

water-cooled jacket. The jacket is connected to a water-cooled condenser.

One end of the jacket is connected to a water-cooled trap containing liquid air.

On the other side of the trap, the jacket is connected to a water-cooled trap.

On the left side of the trap, the jacket is connected to a water-cooled trap.

On the right side of the trap, the jacket is connected to a water-cooled trap.

The jacket is connected to a water-cooled trap containing liquid air.

Water-cooled traps.

## R.1 Preparation of Acetylene and Ethylene by the BASF Process

Gas cylinder 1000 ml.

Acetylene cylinder 1000 ml. containing 100 ml. acetylene.

The apparatus consists of a vertical glass tube (see Fig. 3) which is 10 cm. long.

The tube is connected to a gas inlet tube which is inserted into a horizontal

water-cooled jacket. The jacket is connected to a water-cooled condenser.

One end of the jacket is connected to a water-cooled trap.

The apparatus consists of a vertical glass tube which is 10 cm. long.

The tube is connected to a gas inlet tube which is inserted into a horizontal

water-cooled jacket. The jacket is connected to a water-cooled trap.

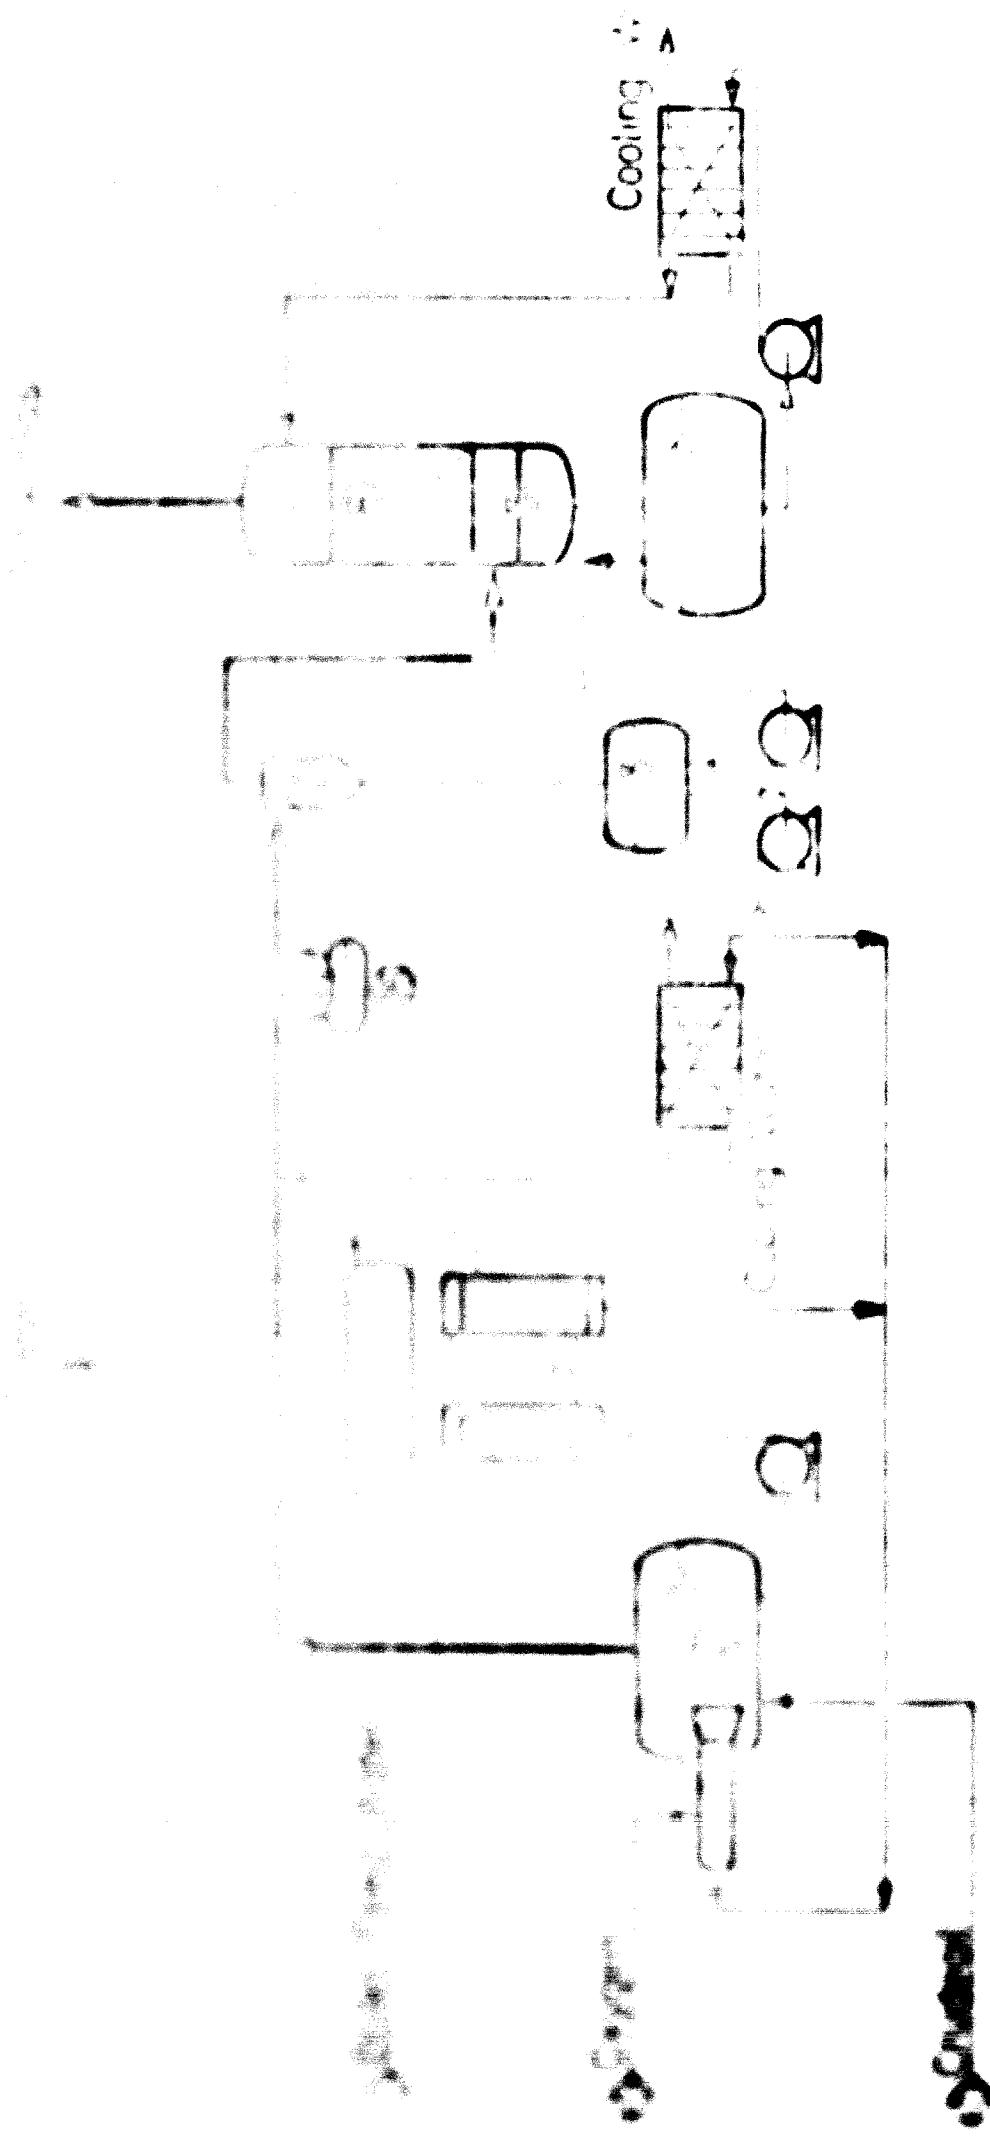

the first time, and the author has been unable to find any reference to it in the literature. It is described here, and its properties are discussed. The method of synthesis is also given.

Figure 6, Part 1, Drawing 1

Process Air - Cooling System  
Modular Scrubber  
Sulfuric Acid Generation Unit  
Cracking - Cooling

# Cracking-Section (BASF)

There are two kinds of gas separation processes for the production of acetylene, which can be seen from the fig. 5. As regards investment and operating costs, there is very little difference between them. In the first case, employing scrubber immediately following the crack still, the yield is low. In this, the major part of the CO<sub>2</sub> and all the H<sub>2</sub>S are removed.

In separation process I, first the remaining CO<sub>2</sub> is removed with sodium bisulfite solution, and the gas subsequently dried with ethanol. By condensation, ethane, propane, propene, isobutane, isobutylene, H<sub>2</sub> and H<sub>2</sub>S. The remaining gas is separated into saturated hydrocarbons by distillation and the unsaturated hydrocarbons by the scrubber. Acetylene is present in the C<sub>2</sub>-distillate which is then separated in a countercurrent column and separated from the other gases.

In separation process II, the gas separator is followed by an N-methyl-piperazine solution. The methyl-piperazine is washed with the C<sub>3</sub>- and C<sub>4</sub>-distillates, and the remaining hydrocarbons are separated in a countercurrent column with benzene. The benzene is then distilled, leaving pure acetylene, which is collected in a gas cylinder, and the residue of which the C<sub>3</sub>- and C<sub>4</sub>-distillates are separated. The benzene is then distilled, leaving the following distribution, which is collected in the last gas in the separator. The water is removed from it by partial condensation at a low temperature, dried and recovered by distillation.

## 2.2 Some technical data

(Feedstock: crude oil)

### a. Purities of the products

	Acetylene % by vol.	Ethylen % by vol.
Plant I	99.8-99.9	99.9

### b. Investment (based on conditions in the Federal Republic of Germany)

- (i) Total cost of a plant for 30,000 metric tons/yr. acetylene (turn key, but without site development and auxiliary plants such as air separation, power station, tank farm, etc.)
- DM 40,500,000. -- (US \$ 10,125,000)

### c. Consumption data per 100 kg acetylene

Reported in process	I	II
Electricity kWh	280	277
Cooling water (25°C to 12°) m³	29.5	30.5
Boiler fuel oil per metric ton	0.97	0.96

d. Composition of materials per 100 kg acetylene

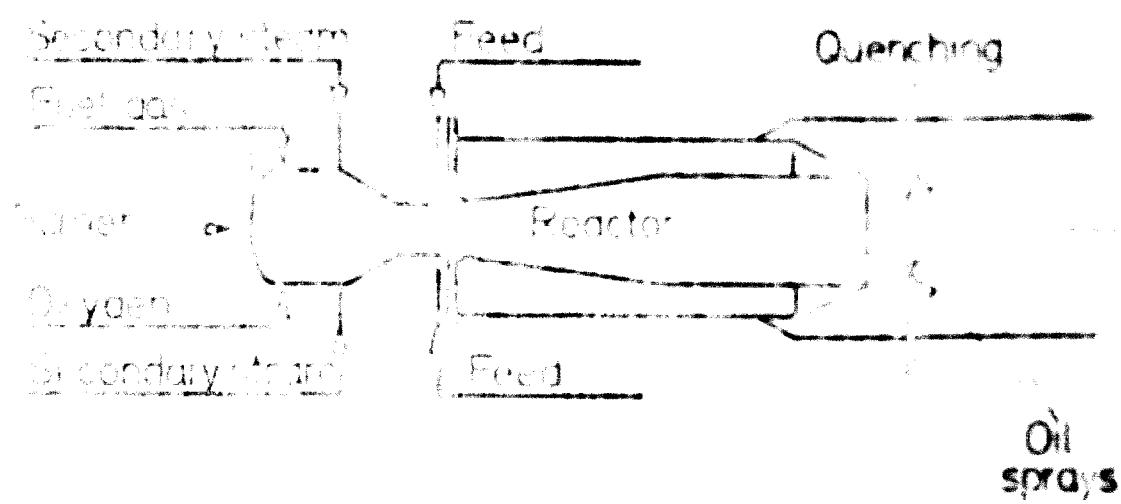

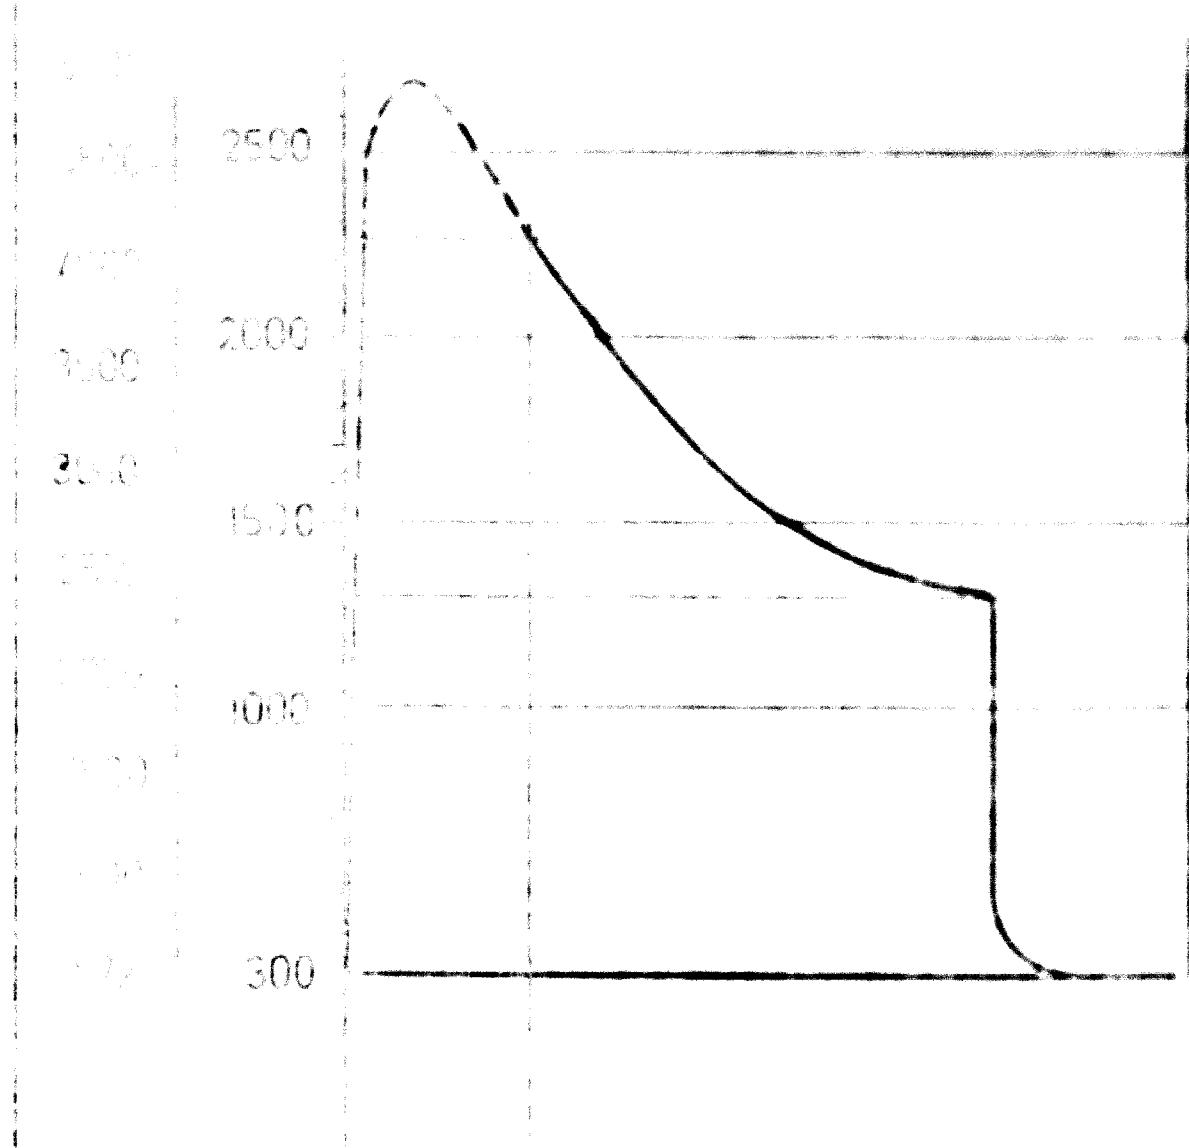

ITEM		I	II
Cone oil	kg	827	827
Oxide	m <sup>3</sup>	510	510
Brominating agent for CO <sub>2</sub>	kg	0.4	0.4
Hydrogen calculated on 100 kg	kg	4	4
Nitrogen	kg	0.3	0.3
Acetone	kg	0.15	-
Water	kg	-	0.5-1
Brominating agent for C <sub>3</sub> -, C <sub>2</sub> -, CO, CO <sub>2</sub>	kg	-	0.35
Compressed air	m <sup>3</sup>	25.	25
Nitrogen	m <sup>3</sup>	50	50

e. Equipment list per 100 kg acetylene

ITEM		I	II
barometric gauge, 10 atm. pressure	metric ton	0.85	0.5
Flowmeter	kg	118	— 118
Line pipe	m <sup>3</sup>	1135	1135
(CO, CO <sub>2</sub> , C <sub>2</sub> -H <sub>6</sub> , 10.3 ppm S)			
C <sub>2</sub> -H <sub>6</sub> and Acetylene carbons	kg	92	92

99. *Hydrogen* is a component of many gases.

100. *Hydrogen* is a component of many liquids.

Experiments show similar reaction conditions being equal, the more the catalyst is aged, the more it shifts in favor of acetylene. A final cracking temperature is reached at which the catalyst drops rapidly to a weight

of about 10% of its original weight.

After a certain time of aging, however, the cracking equilibrium is shifted so far in favor of acetylene that it falls from the process and the cracked product is no longer a liquid (gasoline). A gasoline is obtained

which is very unstable and decomposes almost entirely to a large-thousandth.

After a few hours of aging, the catalyst begins to decompose and the tail gas

is composed of acetylene. This is the reason why the gasoline, soon, is clearly

seen to consist of a large amount of acetylene. The gasoline is now virtually

composed of acetylene and the catalyst is decomposed almost precisely

according to the equation:  $C_2H_6 \rightarrow C_2H_2 + H_2$ . These conditions

are maintained until the catalyst is completely decomposed, after which it operates

as a normal catalyst, i.e., it is again able to decompose acetylene.

The following table gives the results of these experiments:

It is seen that the yield of acetylene is proportional to the heat added or number of crude-

oil molecules reacted. The yield of acetylene is also proportional to the molecular represented

by the catalyst, i.e., the number of molecules of acetylene formed per molecule of naphtha,

which is approximately 1.0. The yield of acetylene is also proportional to the atmospheric

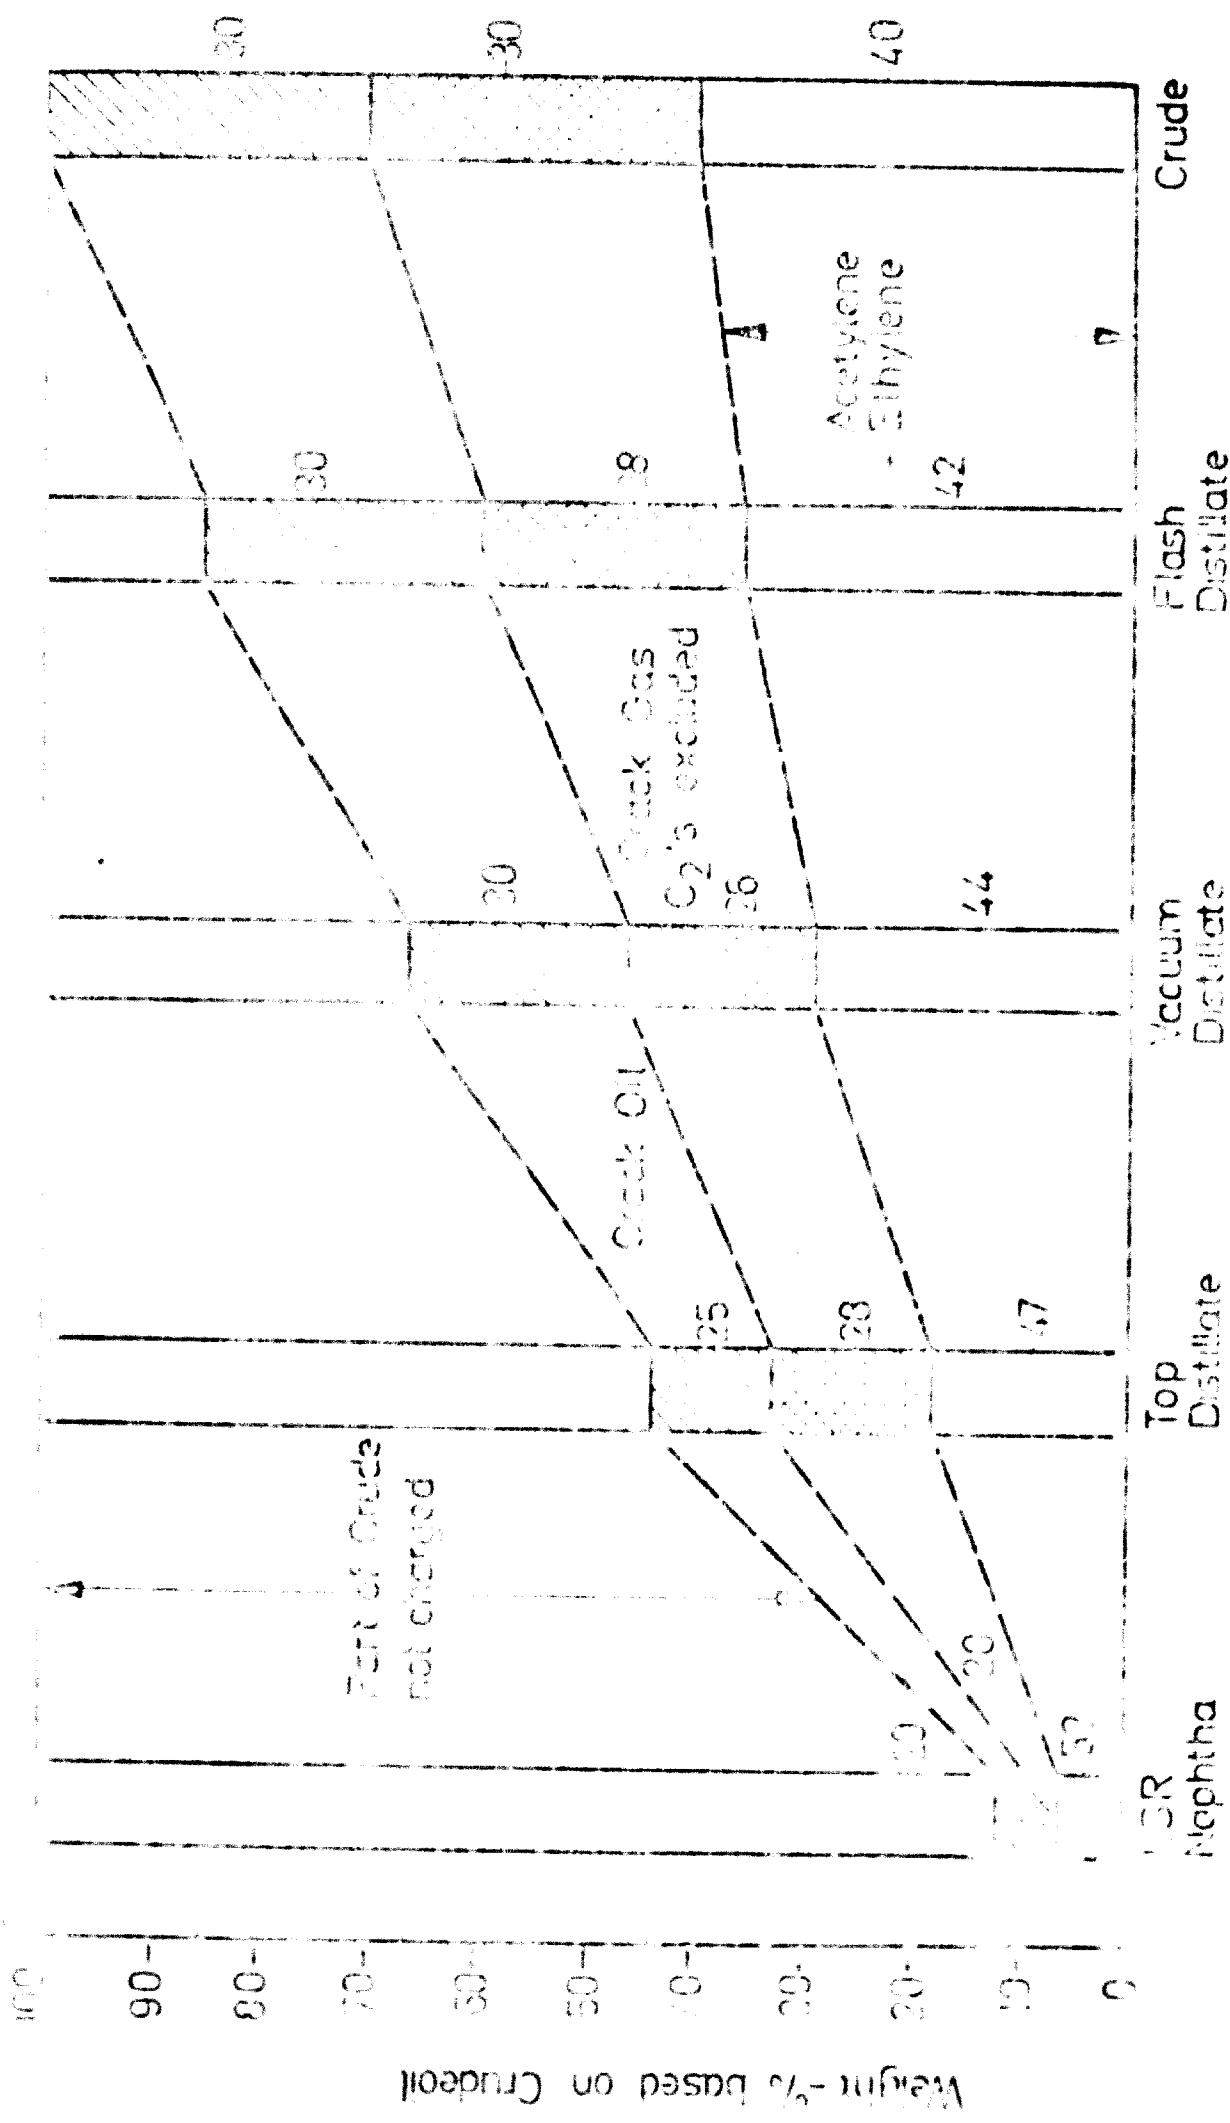

pressure, which is proportional to the number of molecules of gas formed from which

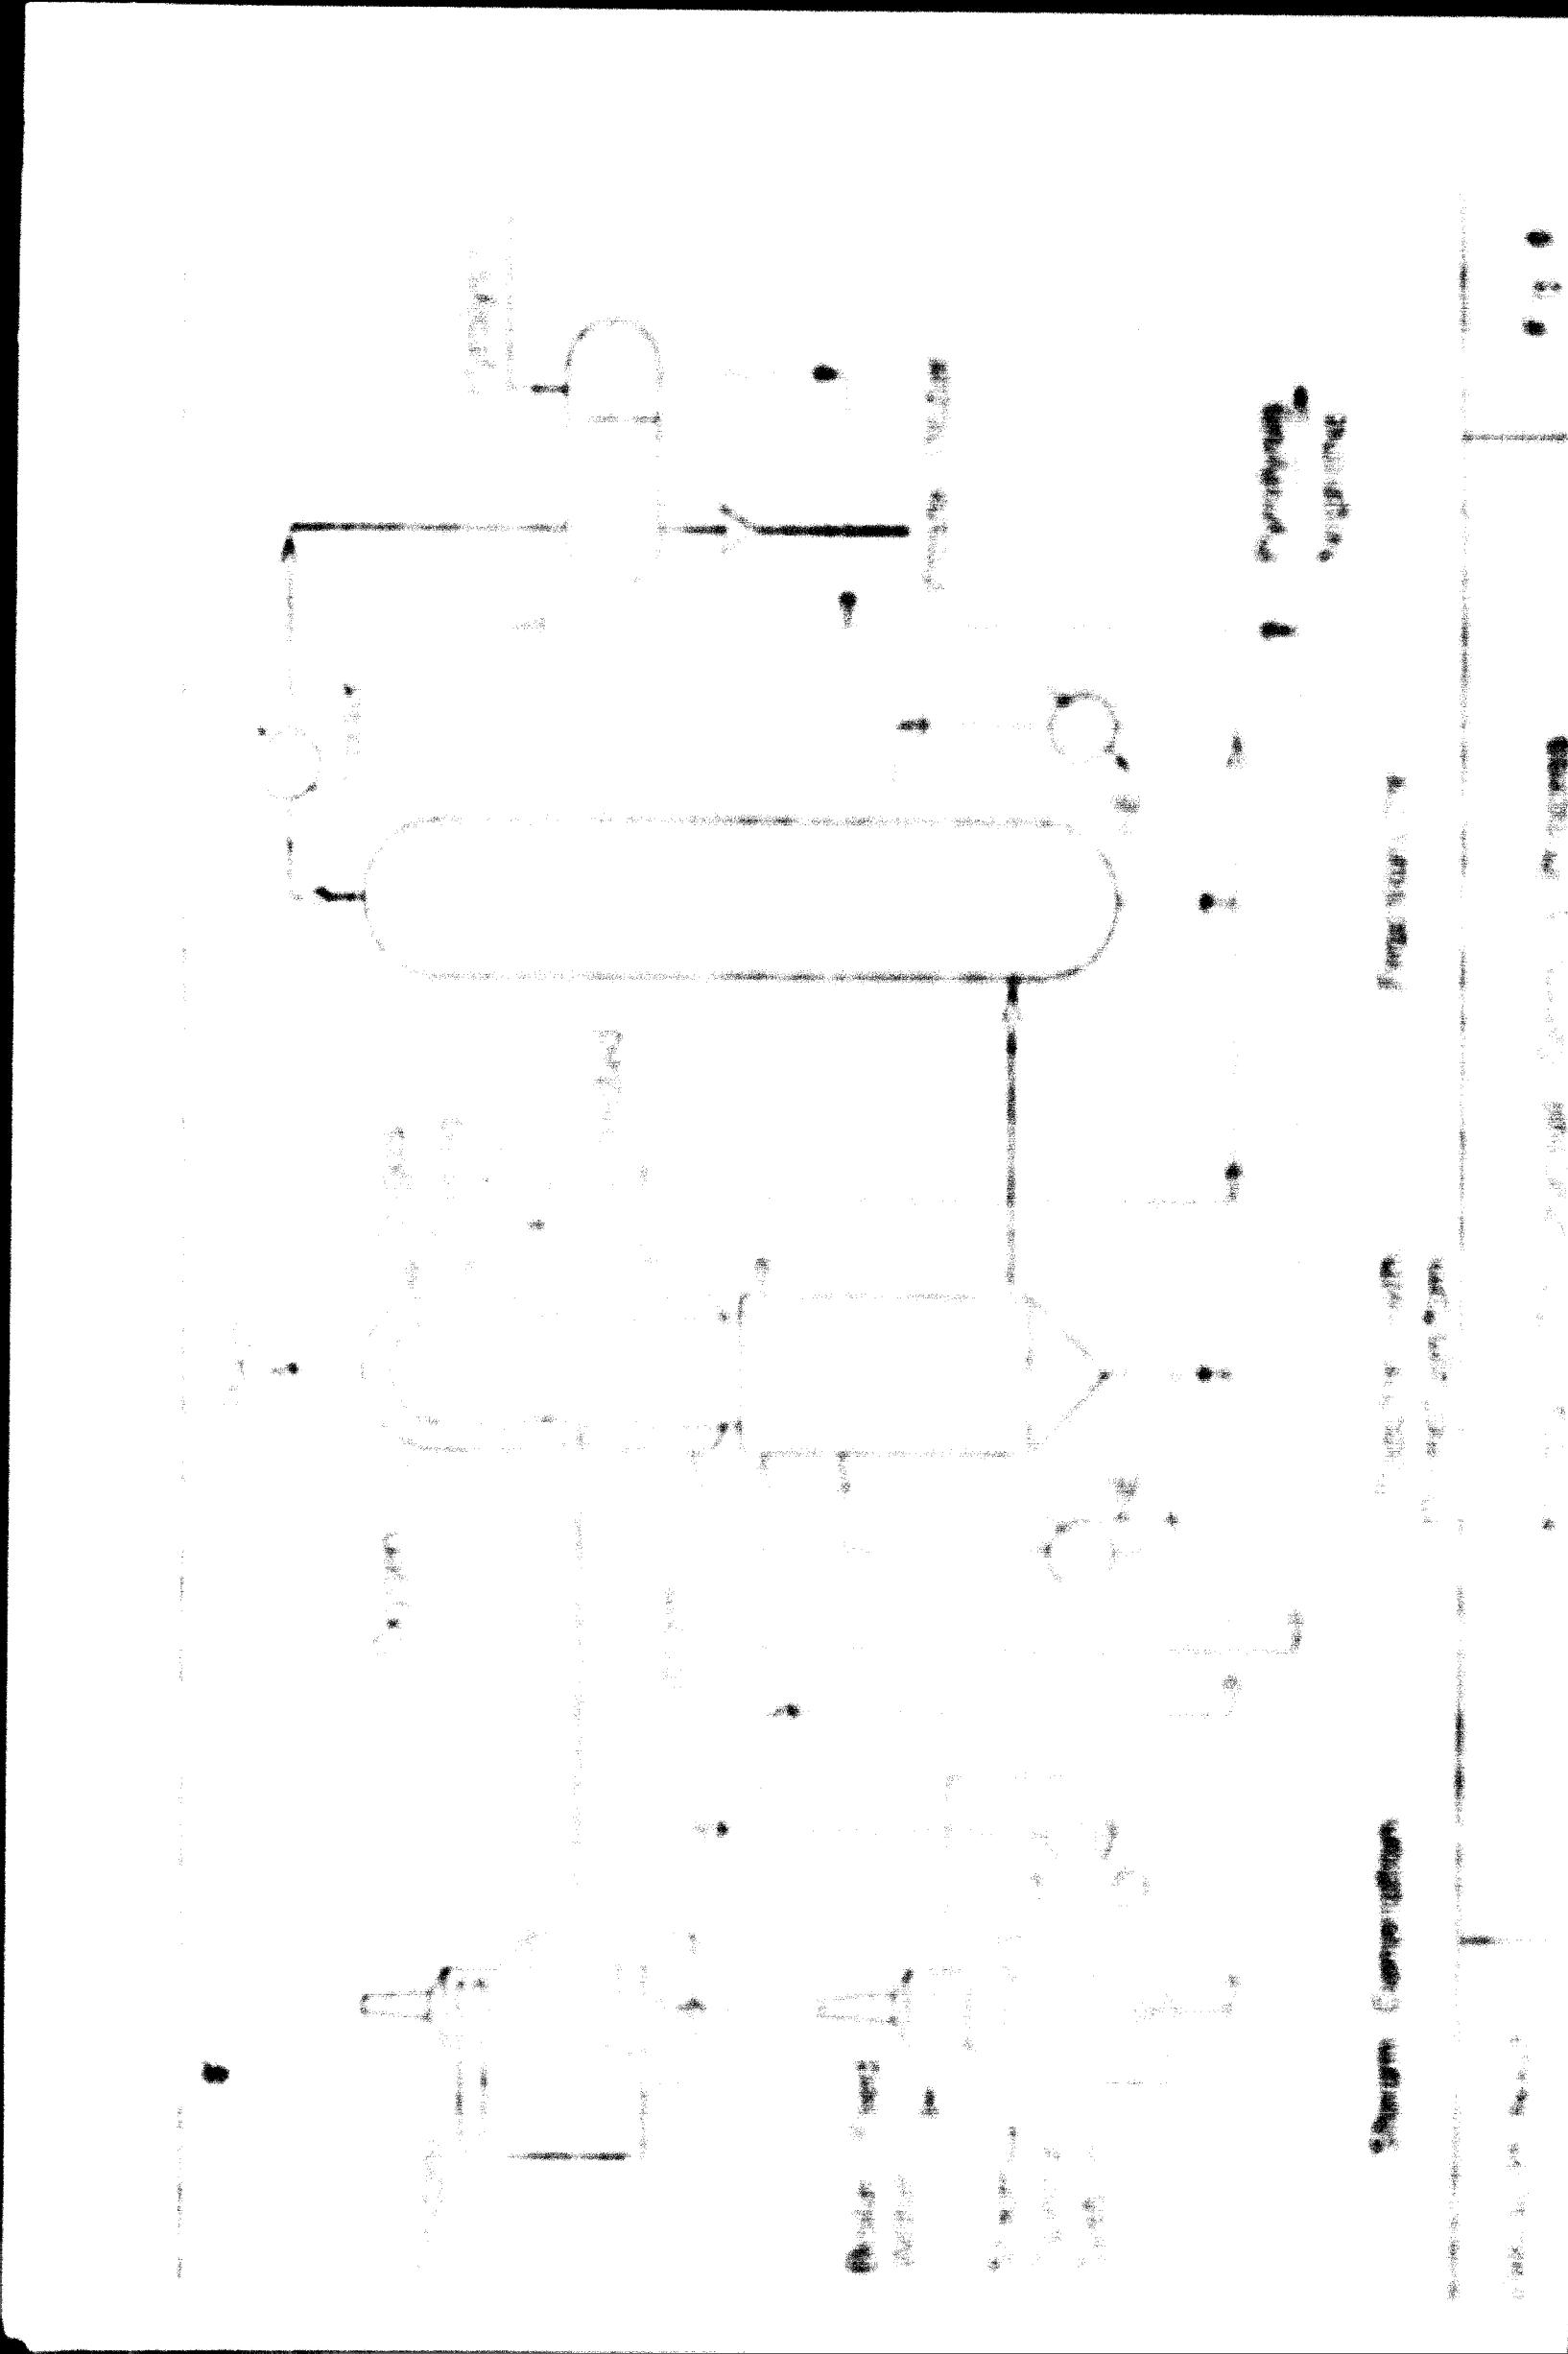

acetylene is formed. The yield of acetylene is proportional to the number of molecules of acetylene formed from which

acetylene is formed. The yield of acetylene is proportional to the number of molecules of acetylene formed from which

acetylene is formed.

Pattern of Products obtained by the Cracking of  
Crude Oil and its Fractions (Boschst-HTP-Process )

4. The BASF Process for the manufacture of acetylene by partial oxidation of propane

4. Principle of the process

Acetylene is obtained by vapourizable hydrocarbons (natural gas, liquified gas or liquid hydrocarbons) and air mixed with excess steam with oxygen. The reaction is carried out in a fixed bed reactor at 1000°C. The catalyst consists of a mixture of cobalt and manganese oxides supported on a porous carrier. The reaction is carried out at a pressure of 100-200 atm. The reaction time is about 10 sec. The reaction products consist of acetylene, water, carbon dioxide, hydrogen and nitrogen. The acetylene is separated from the other gases by absorption in a solvent. The absorbed acetylene is then extracted with benzene. The benzene solution is then washed with water for removal of unabsorbed gases. The acetylene is separated by distillation. The benzene solution is then washed with water to remove traces of benzene. The benzene solution is then dried over calcium hydride and then fractionated by scrubbing selectively with N-methylpyrrolidone and by fractional distillation from the solvent.

The main by-product formed is a gas consisting usually of carbon monoxide and hydrogen which, for example, can be used for **synthesis**.

The above-mentioned products has a slight air exaus of oxygen which, if required, can be increased to 25% by adding propylene oxide.

#### 4.2 Hydrogenation reaction

At first, we will discuss the hydrocarbon mixture formed in the **decomposition stage**.

Hydrogenation is a process in which the hydrocarbons are converted into alcohols, aldehydes, ketones, and other organic compounds.

Hydrogenation is a process in which the hydrocarbons are converted into alcohols, aldehydes, ketones, and other organic compounds.

Hydrogenation is a process in which the hydrocarbons are converted into alcohols, aldehydes, ketones, and other organic compounds.

temperature it is possible to vary within certain limits the ratio of  
water to methane in the cracked gas according to requirements.

A small pilot burner, consisting of a tube 300 ft. long in which  
methane was introduced at the rate of 1 cu. ft. per min., was inserted into the heated  
burner tube. At the downstream end of the tube, a flame was obtained.

#### (a) Methane - Water Ratio - Effect of Water Addition

The following table gives the results obtained with the pilot, cracking,  
and main burners.

#### (b) Methane - Water Ratio - Effect of Water Addition - Flame Being Carried by the Main Burner

The following table gives the results obtained with the main burner, cracking, and water addition.

It will be seen from these tables that the flame length is increased by the addition of water.

It is evident that the addition of water to the cracked gas increases the flame length.

It is also evident that the addition of water to the cracked gas increases the flame length.

It is evident that the addition of water to the cracked gas increases the flame length.

and now the last stage leads to this final step and approach to shaping  
of the structure.

This is the most difficult stage of all because it is here that the whole  
structure begins to take shape and the architect has to make sure that the  
changes made in the previous stages have not affected the original plan.  
This stage requires a lot of time and effort and the architect has to be very  
careful in making any changes.

This stage is also known as the final stage because it is here that the  
architect has to make sure that the structure is complete and ready for use.  
This stage requires a lot of time and effort and the architect has to be very  
careful in making any changes.

The final stage

The final stage is the last stage of the building process.

So one's own material knowledge is not more likely to be true than anyone else's **material knowledge**.

So one's own material knowledge is not more likely to be true than anyone else's **material knowledge**.

1. The first step is to identify the type of error or fault that has occurred. This can be done by examining the system's logs and monitoring data, as well as any user reports of system instability or performance degradation.

2. Once the error or fault has been identified, the next step is to determine its cause. This may involve reviewing the system's configuration files, code, and data structures, as well as any external factors such as network traffic or hardware failures.

3. After the cause of the error or fault has been determined, the next step is to develop a plan for addressing it. This may involve fixing the code or configuration, replacing faulty hardware, or implementing workarounds to mitigate the impact of the error or fault.

4. Finally, the system should be tested to ensure that the error or fault has been resolved and that the system is operating normally. This may involve running stress tests, performing regression testing, and monitoring the system for any signs of recurrence.

### 5.2 hydrogenation of minor amounts of Butadiene remaining in C<sub>3</sub>-raffinate

The product C<sub>3</sub> is usually rich in Butadiene so that in general pure butadiene can be obtained therefrom. The remaining C<sub>3</sub>-out (raffinate) still contains some butadiene, along with the normal hydrocarbons. Also C<sub>3</sub>-out may contain some C<sub>4</sub>-hydrocarbons which may or may not contain butadiene in significant amounts. For the sake of chemical treatment this C<sub>3</sub>-out is best to be directed to a polymerization plant so that it is recommended to take the C<sub>3</sub>-out to a polymerization plant. The use of hydrogenation has proved to be very good. The more of operation in the small one for the cold polymerization, the especially adapted to the plant to be fulfilled because of the small amount of polymerization it is to be used that the C<sub>3</sub>-out is to be directed to a polymerization plant, that is, that the polymerization plant is to be directed to the C<sub>3</sub>-out.

By the use of such a polymerization plant it is also possible to combine the C<sub>3</sub>-out and C<sub>4</sub>-out with the C<sub>3</sub>-out to minimize loss of

n-butene-1 into n-butene-2. By performing the process in this way a distillation separation between isobutene and n-butene-1 becomes possible in distillation column 1. The separated product n-butene-2 is sent off to the non-isomerization unit. The product isobutene is collected and is returned together with n-butane to the distillation bottoms. The major part of the isobutene in the original feed is partially converted for further chemical processing.

#### TABLE I Pyrolytic Products of 1,3-Butadiene

After the first heating of 1,3-butadiene at 100° C., the hydrocarbon fraction more or less completely disappears, leaving a solid residue. The composition of this hydrocarbon residue is given in Table I. It is seen that the hydrocarbon is 1,3-butadiene (TIB), which is the most abundant product. It is evident that the residue formed for the first heating is not a saturated hydrocarbon, but is probably hydrogenated further by oxygen in air. It is probable that the oxygen is present in the full hydrogenation of the 1,3-butadiene residue. The hydrogenated hydrocarbons are listed in Table I. Table 4 shows the yields of the products.

The hydrogenated 1,3-butadiene is pure 1,3-butadiene, absolutely free from oxygen and is soluble in most solvents in the usual solvents, mainly in aliphatic and aromatic hydrocarbons. The hydrogenated product is a colorless liquid which, added to pyrolyzed pyrolysis

These hydrocarbons are all typical representatives of the alkenes which are known as *olefins*.  
The name "olefin" is derived from the Latin word *oleum*, which means oil.

#### Olefins - Alkenes

##### Alkenes - Double Bonds

Alkenes are hydrocarbons containing double bonds.

Alkenes are also known as *olefins*.

(Alkenes are also known as *olefins*.)

(Alkenes are also known as *olefins*.)

#### Alkenes - Double Bonds - Particularity of Butadiene

##### from Yerkes et al., 1953

Butadiene is an important secondary product formed during the production of styrene. The following equations illustrate the manufacture of styrene. In the first equation, the structure of the following "poly-cis" pentad is given. In parentheses, the percentage of total acidity, one under 50 percent, is given for each propylene polymerization process.

Butadiene is an important secondary product formed during the production of styrene. The following equations illustrate the manufacture of styrene.  Polyacrylate polymerization (Acrylate process)

and so it is important to make sure that all of the hydrocarbons are removed from the system. This is done by first heating the system to about 400°F and then pumping air through the system. This will remove most of the hydrocarbons. Then, the system is cooled and sealed. Finally, the system is evacuated and the pressure is checked. If the pressure is too high, then the system is heated again and the process is repeated until the pressure is low enough.

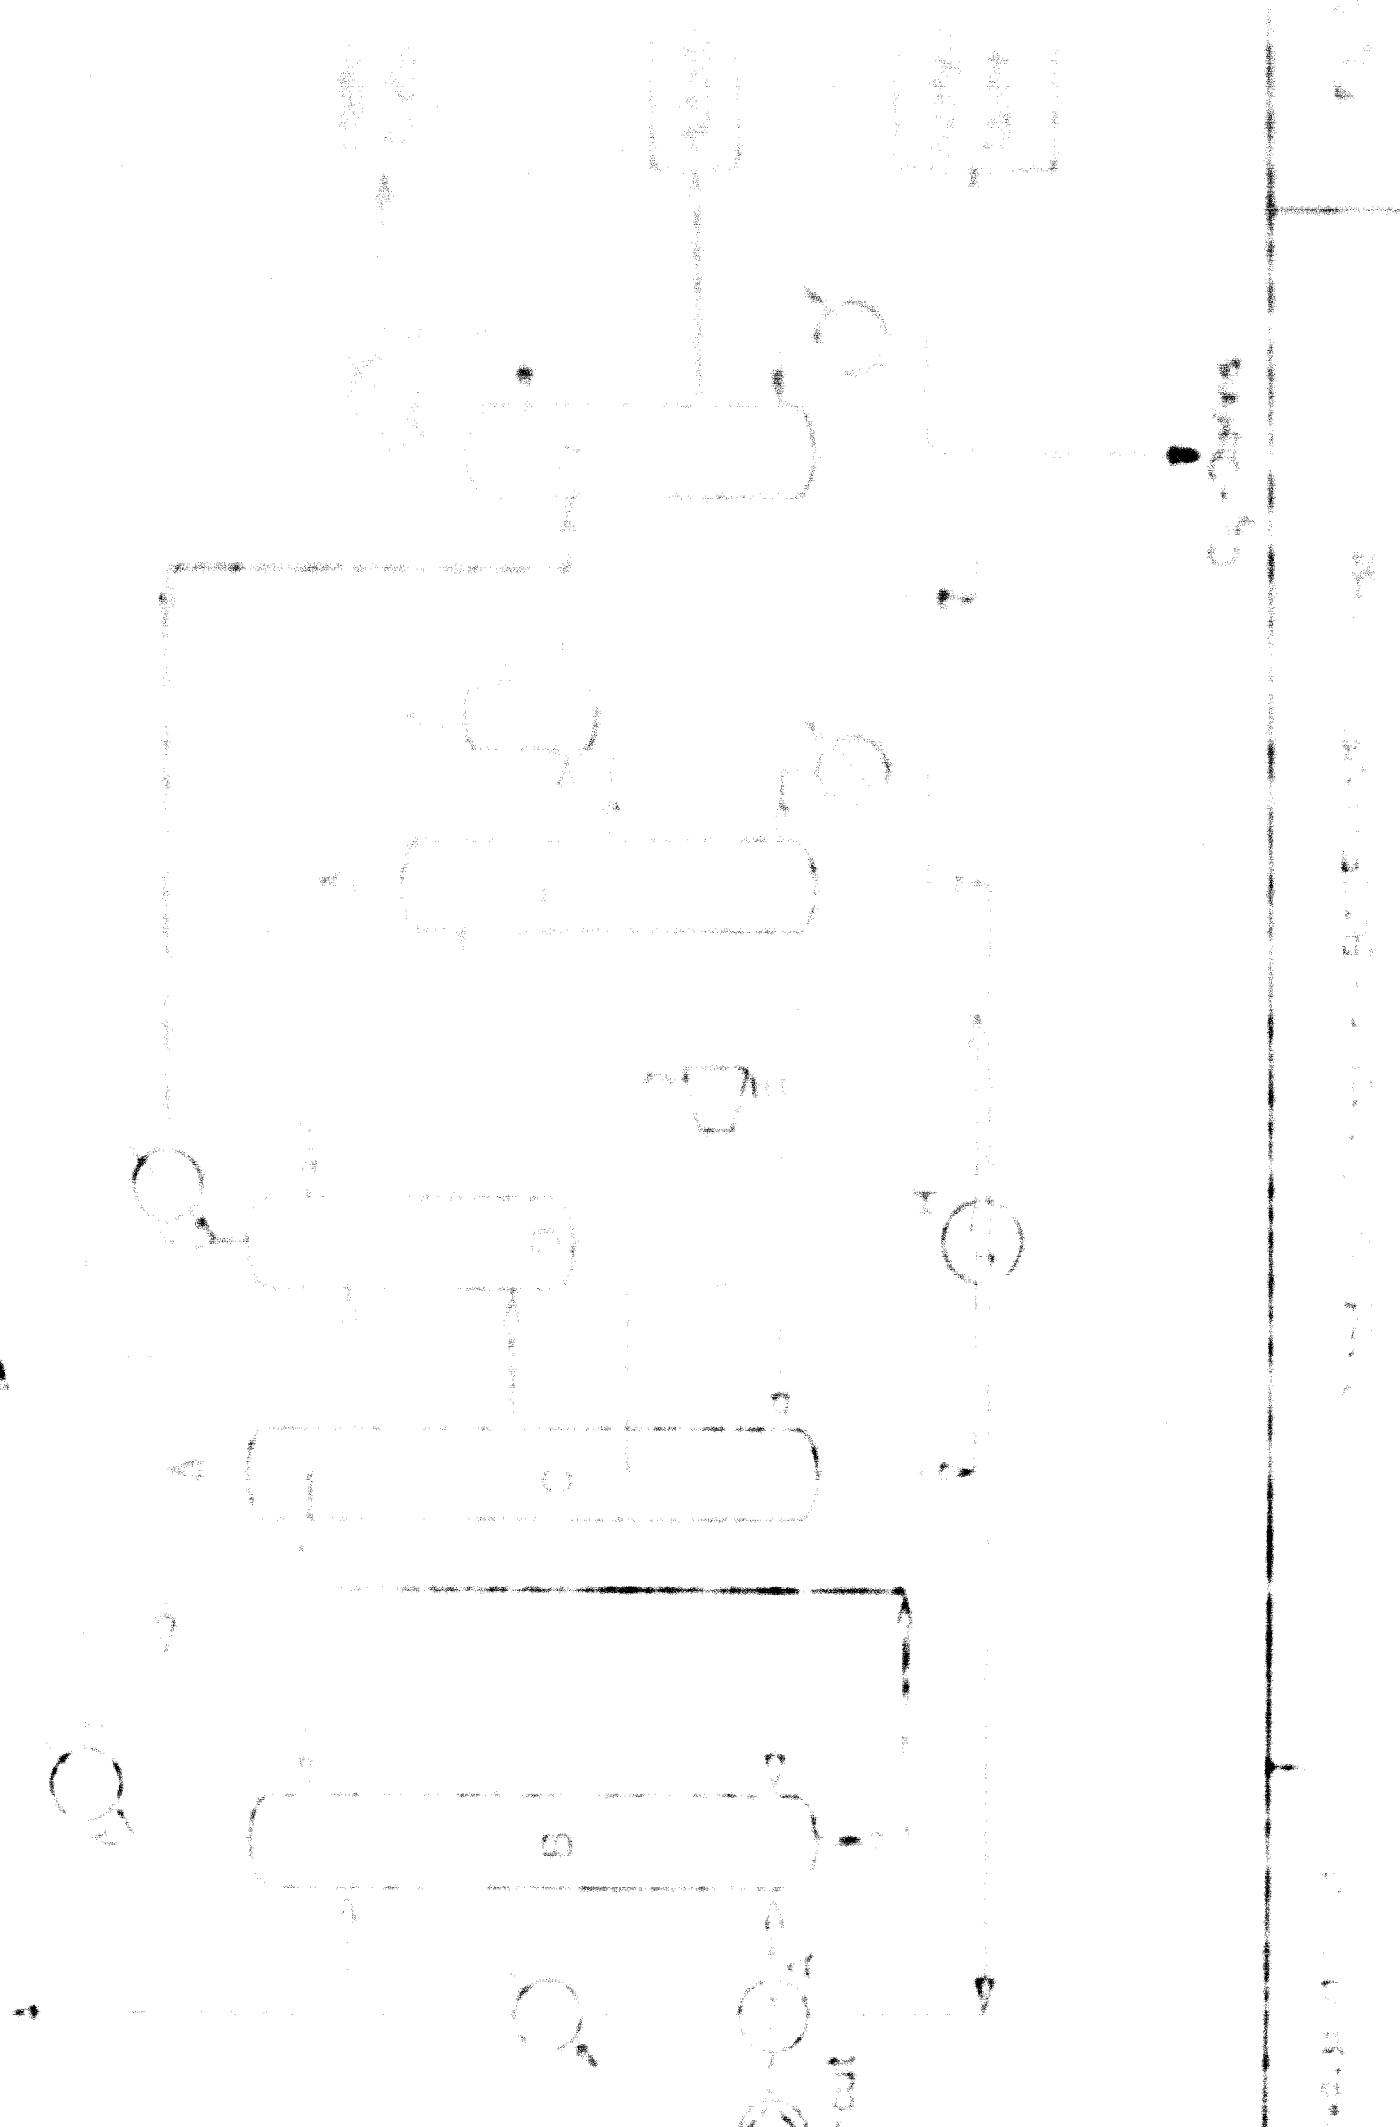

This method of purifying the system is called "vacuum distillation". It is a very effective way to remove hydrocarbons from a system. However, it is also a very expensive way. Therefore, it is only used for systems that require a very high level of purity.

In addition to the vacuum distillation method, there are other ways to remove hydrocarbons from a system. One way is to use a solvent. A solvent is a liquid that can dissolve hydrocarbons. When the solvent is added to the system, it will dissolve the hydrocarbons. Then, the solvent is removed, leaving the hydrocarbons behind. This method is called "solvent extraction".

Another way to remove hydrocarbons from a system is to use a filter. A filter is a device that has small holes in it. When the hydrocarbons pass through the filter, they get stuck in the holes. This leaves the system free of hydrocarbons. This method is called "filtering".

There are many other ways to remove hydrocarbons from a system. However, the most common and effective way is to use vacuum distillation.

Table 1 - continued

Isobutene (1)	43.7	- 4.41°C
Isobutane	1.1	-

The process described by us for the recovery of isobutene makes it possible to use oil reservoirs containing pyrolytic gases as feedstock. An example of such a situation is the following: the product known as "Pyrolytic Gasoline" (PG) is introduced into a reactor known as the "Pyrolytic Gasoline Reactor" (PGR) in batches. The yield in PG = 95%, very little isocbutene is formed (less than 1% calculated on the total feedstock).

The separation of isobutene from butane-isobutene mixtures such as those from the PGR, CCR and the pyrolysis, is not possible by normal distillation due to the small proportion of isobutene (not more than Table 1).

After being separated, the following relative values for the economical separation of isobutene from butane are obtained: however there is still the possibility of separating isobutene by distillation taking into account the great chemical reactivity of isobutene, which can be used advantageously.

Thus, in our opinion, the most suitable chemical reaction for the separation of isobutene is made by the addition of water to tertiary alcohols (tertiary alcohols + water).

#### THE PROCESS OF ISOBUTENE RECOVERY

The process of isobutene recovery (fig. 10) can be divided into several stages: absorption, separation, absorption, separation and if necessary,

distillative purification of the tert.-butanol, dehydration and rectification of the isobutene. The isobutene is selectively absorbed from the benzene butene mixture at about  $30^{\circ}\text{C}$  in a bubble column A with the aid of the sulphuric acid-containing absorption solution. Tert.-butanol is being formed. The absorption solution flowing from the absorber passes into a distillation column B in which the tert.-butanol formed is distilled at reduced pressure as an azeotrope (with water). The absorption solution is recycled to the absorber after cooling in C.

The absorption solution flowing into the distillation column contains a small amount of physically dissolved n-butenes. The overhead vapors of the column B reflux contain, besides the tert.-butanol-water-azeotrope small amounts of n-butene which are separated by distillation in a second, smaller column. These n-butenes as well as small amounts of isobutylene formed in the bottoms of column B by hydrolysis of the tert.-butanol, are separated from the tert.-butanol-azeotrope in B and recycled to B. The tert.-butanol-azeotrope is drawn off from the bottoms of B and introduced into a heated dehydrating furnace. Dehydration takes place in the presence of activated aluminium oxide at  $250^{\circ}\text{C}$ . The reaction mixture condensed in condenser G is separated in separator H into the two reaction products isobutene and water. The isobutylene is then freed from traces of higher boiling contaminants (diisobutene, tert.-butane) by fractionating in column J.

### 3.2 Investment, consumption figures and manufacturing costs

#### Investment (Initial factory limits)

Dr. 4,500,- (US \$ 1,125,000)

(Price in Federal Republic of Germany, without taxes, engineering fee)

#### Feedstocks:

Butene mixture (50 wt % isobutene) 13,370 metric tons/yr

Operating hours per year: 8 000

#### Products:

Isobutene-isobutylene 5 000 m.t./yr

Isobutylenes: 9.2%

Isobutanol: 0.05%

Toluol-Isobutanol + diisobutylene: 0.01%

#### Field:

#### Consumption figures (per ton isobutene)

Steam (4 atm. pressure) 2.5 m.t.

Electricity: 500 kWh

Natural gas: 140 m<sup>3</sup>

Cooling water: (25°C) 200 m<sup>3</sup>

Storage tanks: 100 m<sup>3</sup> (100% isobutene)

Operating costs calculation

DM per m.t.

Steam (DM 6/m.t.) 15.00

Electricity (DM 1/100 kWh) 20.00

Natural gas (DM 6.5/100 m<sup>3</sup>) 9.10

Cooling water (DM 2/100 m<sup>3</sup>) 8.00

Chemicals 2.00

Operating costs DM 54.10/m.t. isobutene

US \$ 13.525)

Capital costs (4 year capital return) DM 1,125,000/yr

i.e.DM 187.50/m.t. isobutene

Maintenance (4 % of investment costs/yr): DM 180,000/yr

i.e.DM 30 / m.t.isobutene

Personnel (2 men per shift) DM 10 /hr

DM 13.35 /m.t.isobutene

Overhead (isobutene in the butene mixture):

DM 100 /m.t.

Manufacturing cost DM 385 /m.t.isobutene

(US \$ 96.25)

Isobutene Intermediates - DM Process

Following is a copy on the recovery of butadiene from pyrolysis C<sub>4</sub>-guts

It was found that the yield of the DM-process is also suitable for the

recovery of isobutene from pyrolysis C<sub>4</sub>-guts. It was found that a propane

of high purity and in a good yield can be recovered from C<sub>5</sub>-cuts (table 1). It was found to be advisable to place an MP liquid-liquid extraction step before the C<sub>5</sub> counter-current gas scrubbing step.

Table 1

Qualitative analysis of a cyclooctadiene-containing pyrolysis C<sub>5</sub>-cut

	wt %
Unhydrogenated	0.0
Cyclopentane	26.1
Cyclohexane	24.1
Cyclohexene	4.2
1,3-Cyclohexadiene	11.0
1,4-Cyclohexadiene	13.7
1,5-Cyclohexadiene	1.6
1,6-Cyclohexadiene	0.1
1,7-Cyclohexadiene	5.8
1,8-Cyclohexadiene	2.5
1,9-Cyclohexadiene	2.2

Estimated total cyclohexadiene

The cyclohexadiene content of the pyrolysis C<sub>5</sub>-cut is 13 to 14% on average.

It is recommended that the C<sub>5</sub>-cut be recovered via liquid-liquid extraction from

MP solvent.

The following are approximate dimensions of the counter-current gas or rubber:

1.0 m length, 1.0 m diameter, 1.0 m height of the coil - the required amount of

Circulating solvent, corresponding to the isoprene concentration, is dependent on the amount of  $C_4$ -cuts to be used as feedstock. In the case of isoprene recovery, therefore, a relatively large plant would be necessary in addition to the moderate isoprene amount. In addition, the entire  $C_4$ -cut would have to be vaporized which in turn would require a large amount of steam for heating. In comparison, however, to separate the pentanes which are contained in amounts between 40 and 50% in the  $C_5$ -cut, a considerably small amount of solvent would be needed for a liquid-liquid extraction by the use of water-containing N-methylpyrrolidone. This makes it possible economically to absorb the total isoprene including the other  $C_5$ -olefins in N-methyl-pyrrolidone by means of such a liquid-liquid extraction. A proportion of the pentenes is dissolved in the N-methylpyrrolidone at the same time.

The N-methylpyrrolidone which contains the isoprene, the other  $C_5$ -diolefins and part of the pentenes, as shown in the flow sheet (fig. 11), is freed from the "isocyclic hydrocarbons" by introducing it into the head of a distillation column, heating and boiling in the usual way in the bottom of this column. Here in this column, under the conditions of counter-current circulation, the isoprene is separated from the other accompanying components. This separation process, in contrast to separation of the pentanes, requires a relatively large number of trays, but this is quite feasible in a distillation column.

The amount of solvent was considerably reduced by removal of the pentanes in the preceding liquid-liquid extraction. The mixture of pentenes and a small amount of isoprene collected as overhead of the column is condensed

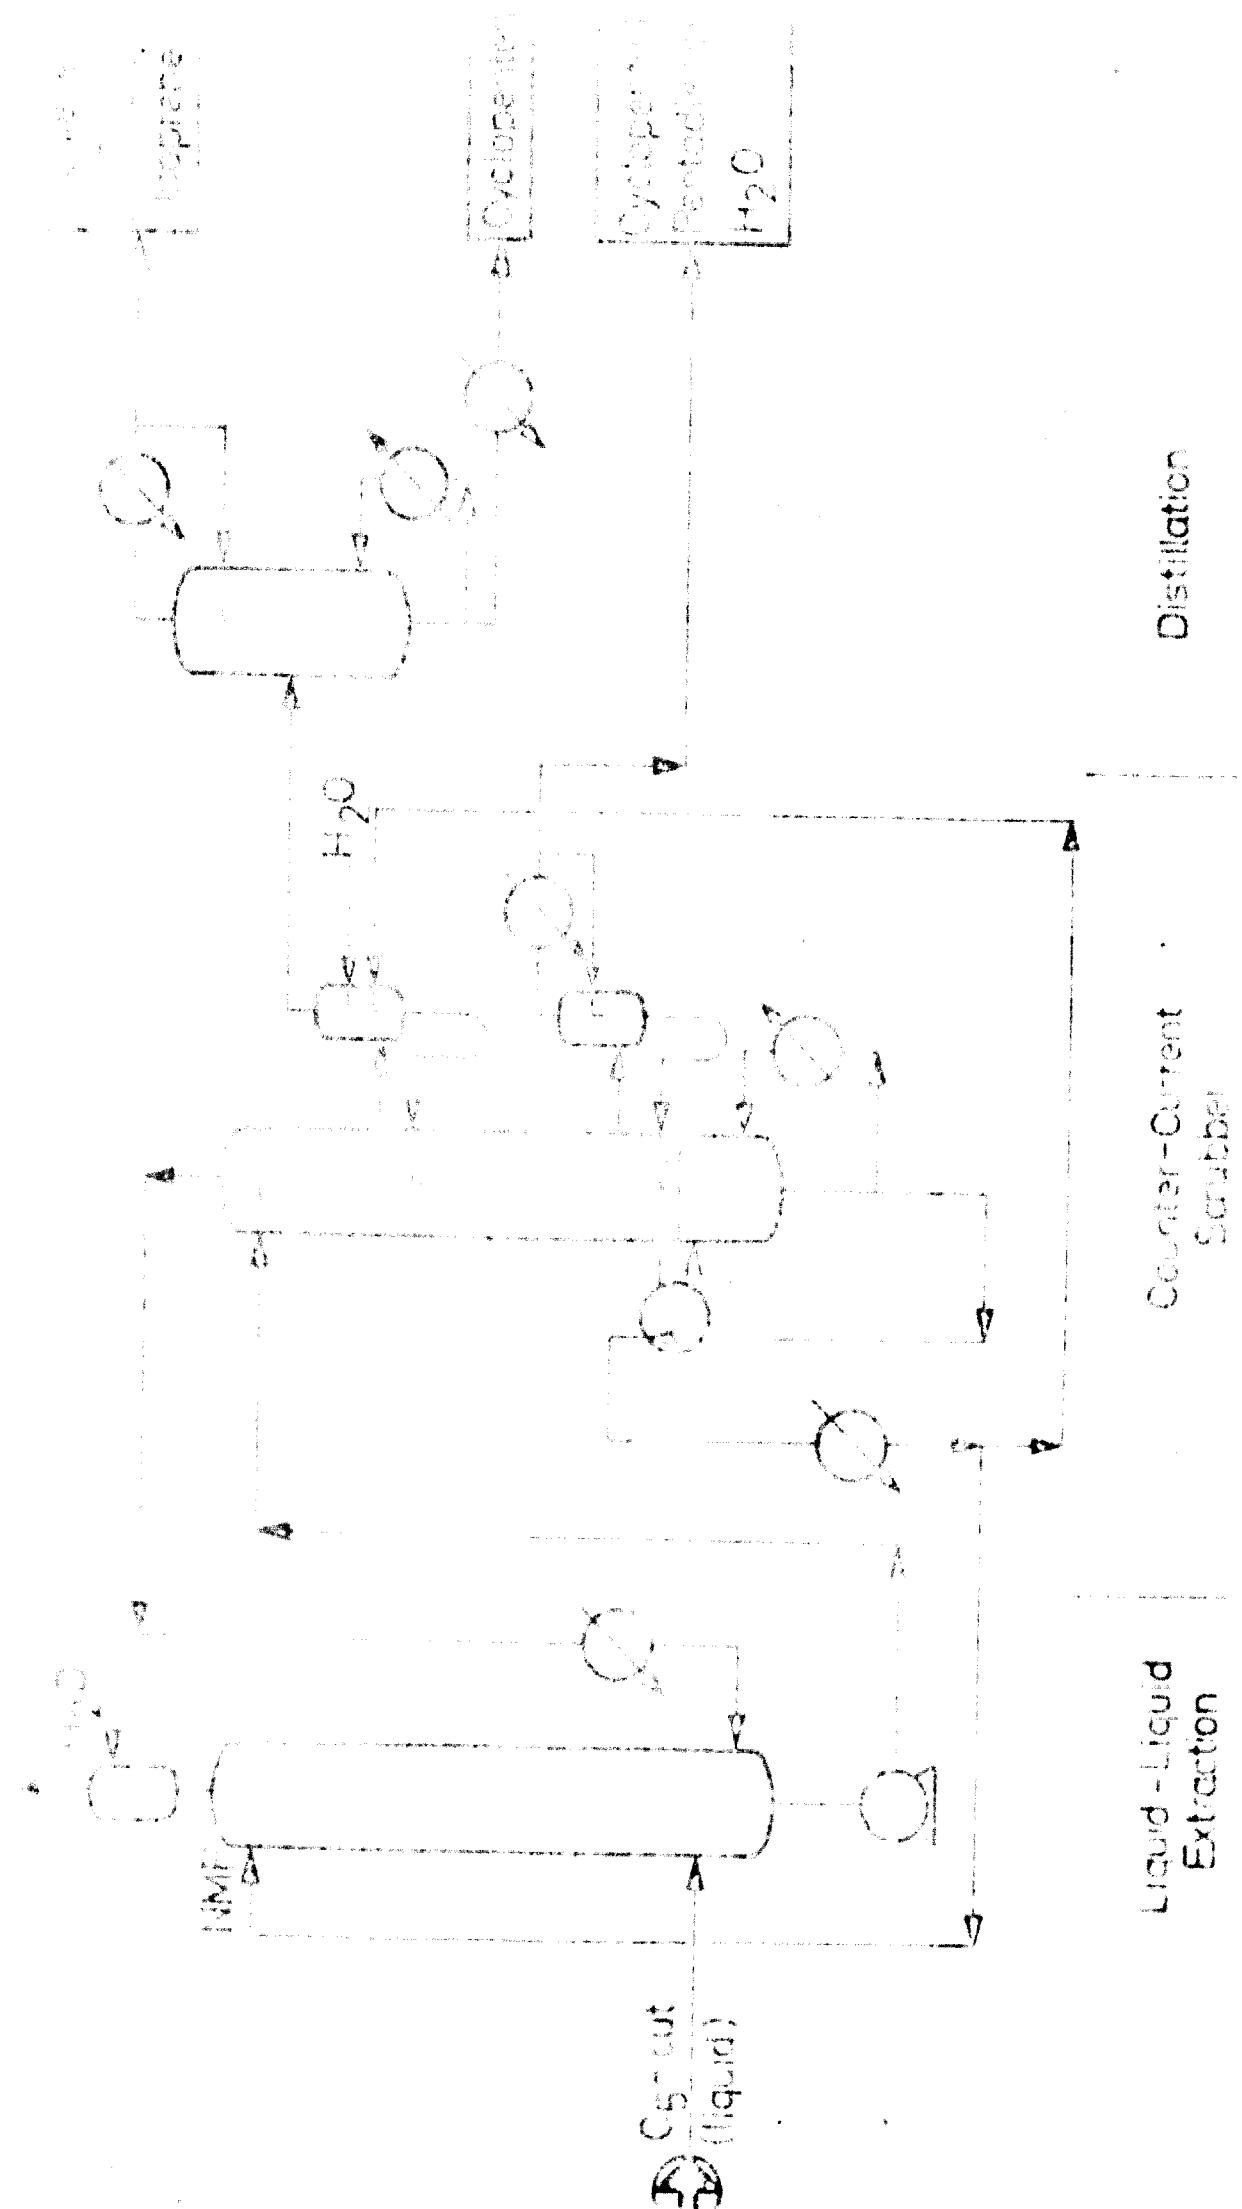

Fig. 1

Process Flow Sheet

and recycled at a suitable level into the liquid-liquid extraction column. Corresponding to their solubility, the C<sub>5</sub>-hydrocarbons accumulate at higher levels in the column from which they are drawn in the usual way as side streams.

The isoprene is removed as the uppermost side stream. If the isoprene side stream contains excessive amounts of pentadienes, cyclopentadiene or C<sub>5</sub>-hydrocarbons, i. e. compounds with higher solubility, these are removed as side streams. In addition to scrubber, as has already been shown previously, for the removal of acetylene in the butadiene recovery.

Column T-1 is not sufficiently selective for separation of the isoprene-isopentene. Since the boiling point difference of these is only 10° F., however, 10%, i. e. the relative volatility is very high, separation of the accompanying component from the diolefin is possible with a given selectivity, like in the system butadiene-isobutylene.

The studies carried out employing this process on an industrial scale have not yet been completed. However the results obtained so far indicated that the limits for the recovery of isoprene of high purity from cracked naphtha distillates are very favorable.

#### 3.2.2. Pyrolysis of Naphthalene-Liquid-Phase "Cold Hydrogenation"

Pyrolysis of naphthalene is a severe thermal reforming, which produces naphthalene - a thermal reformat which has to be refined to meet motor gasoline specifications. Thus indeed the use of the pyrolysis product as motor gasoline blending component is a common one.

After about 10 minutes of shutdown of the reactor, after leaving the reactor, the vapor from the reactor is sent to the separator tank which was mentioned, and in an intermediate tank, the vapor is cooled and separated from the water and freed in a separator tank.

The water which is sent to the separator tank is sent to the hydrocracker feed tank. This is because the water which is sent to the hydrocracker feed tank is the earliest. Pure water is sent to the hydrocracker feed tank, and water containing less than 50% by volume of hydrocarbons is sent to the separator tank.

Hydrocracker feed tank is connected to the separator tank. The separation may be carried out in the separator tank. The water which is sent to the hydrocracker intermediate tank is sent to the separator tank. The water which is sent to the separator tank is sent to the hydrocracker intermediate tank. The waste gas which is sent to the separator tank is sent to the hydrocracker intermediate tank. The waste gas which is sent to the hydrocracker intermediate tank is sent to the separator tank.

c) Consumption of utilities and materials:

For one metric ton of pyrolysis naphtha employing combined air and water cooling.

Electricity	20 kWh
Steam	0.1 m.t.
Cooling water	5 m <sup>3</sup>
H <sub>2</sub> -consumption	40 - 80 m <sup>3</sup>
Catalyst consumption	0.02 kg

### 11.3 Economy

The calculation is based on a plant for an annual throughput of 100,000 tons of pyrolysis naphtha which is connected to a selective hydrogenation unit operating by the BAYER process (Federal Republic of Germany conditions).

Investment for the key-turn plant	DK	2,600,000
	US \$	650,000
Interest and amortization 15 %		48,75
Maintenance	3 %	9.75
Personnel (1 man per shift) and supervision		7.50
Hydrogen (less calorific value credit for waste gas)		44.00
Utilities and other operating materials		32.00
Total manufacturing costs	DK/hr	142.00
	DK/m.t.	11.35
	US \$/m.t.	2.34

O. Reitz, "Treating Aromatic By-Product light Oils from Pyrolytic conversions by the R.S.-Solvay-Process for Light Oil ~~effluent~~", Proceed. 5th World Petrol. Congress, Vol. III, Paper 17, 1959.

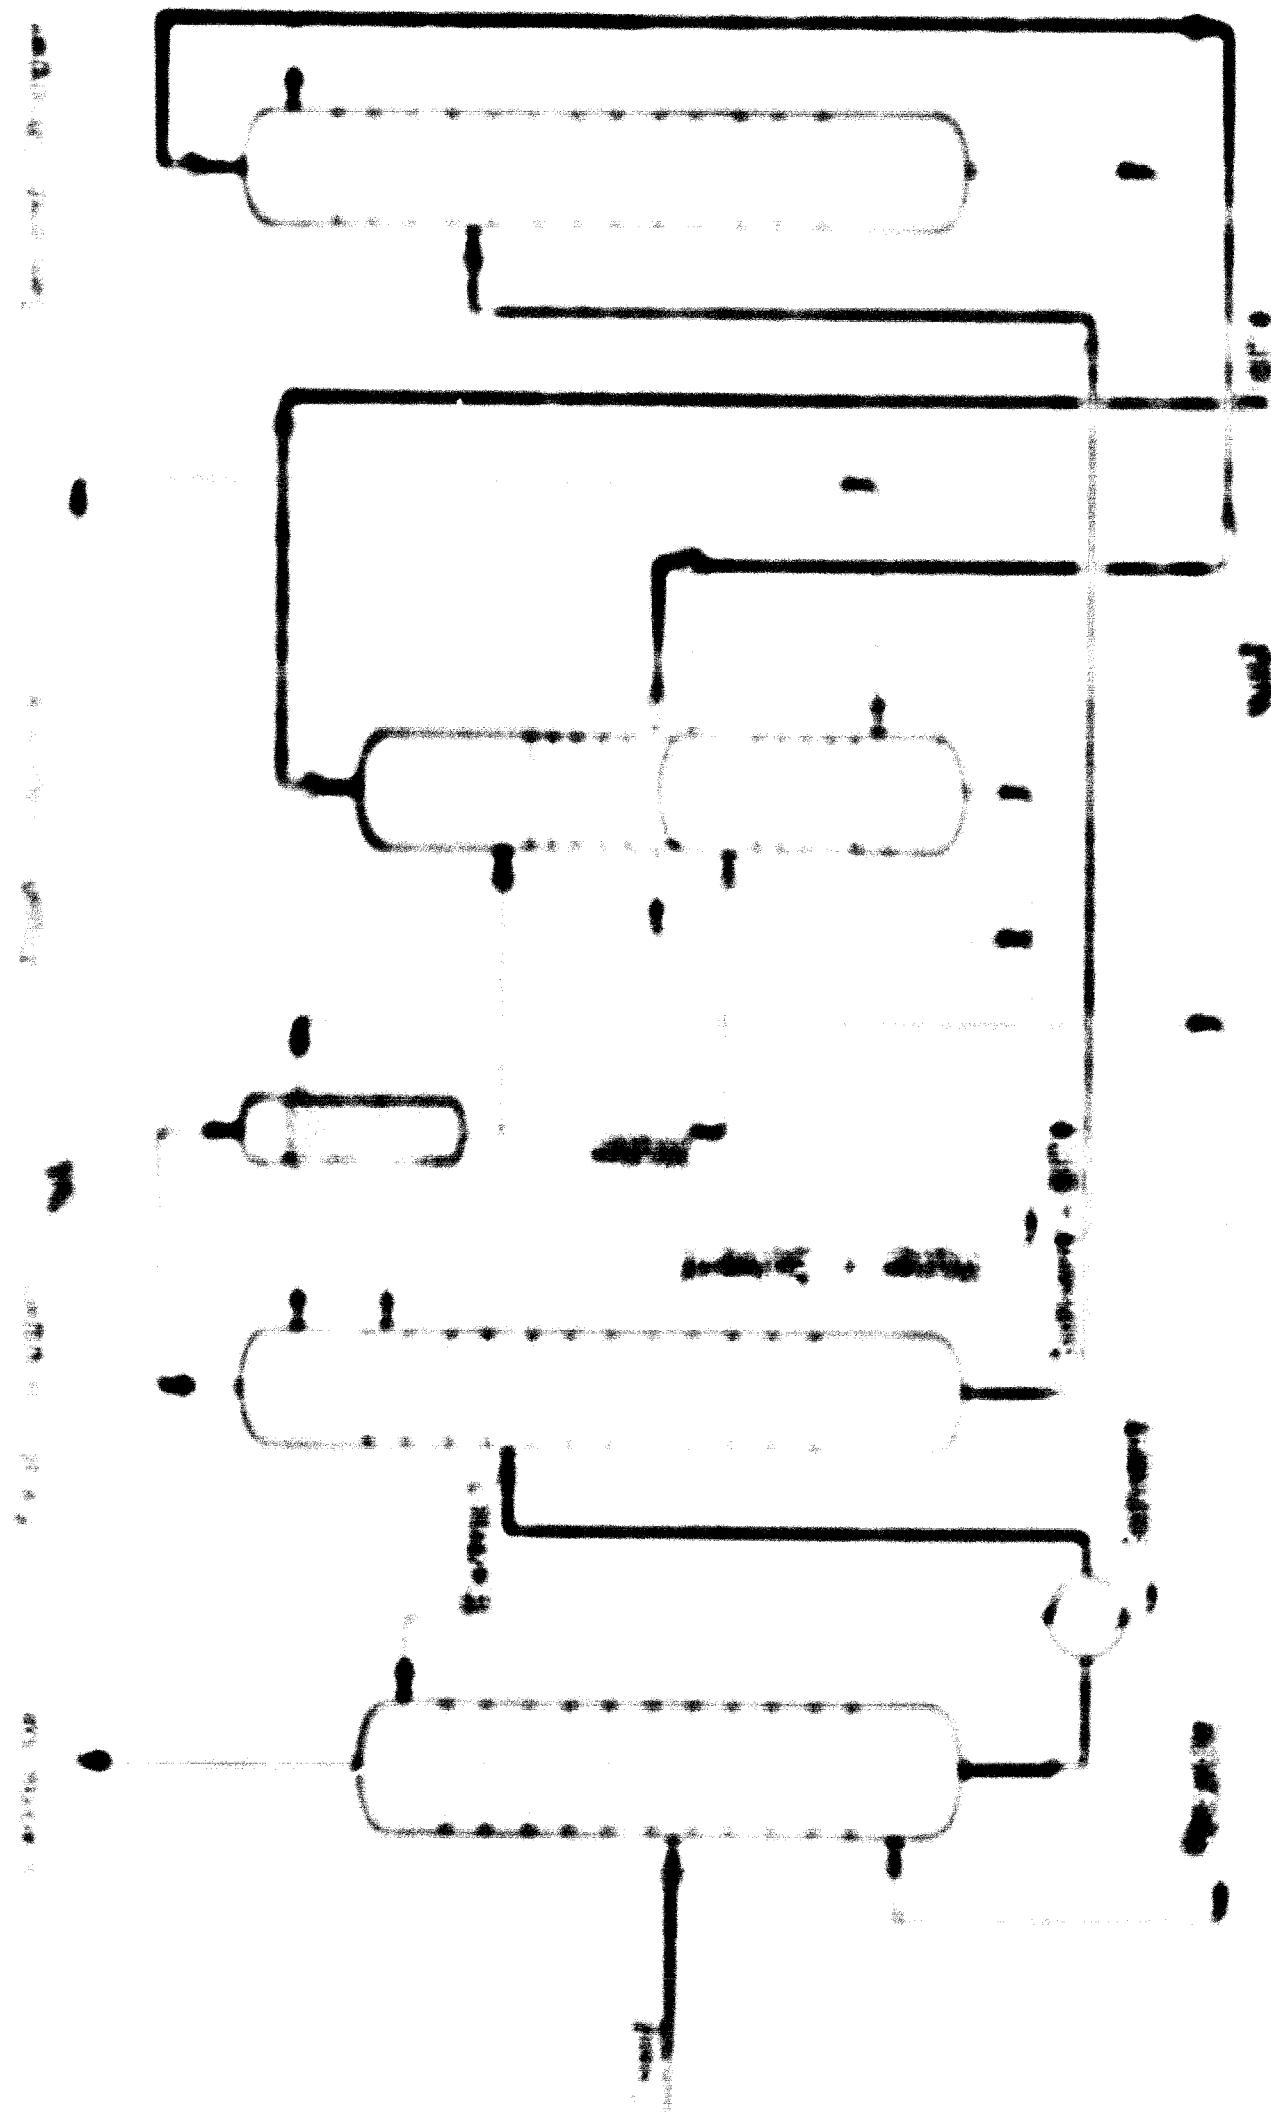

### 12. Pure Aromatics Extraction-Lurgi 'Trosolver' Process

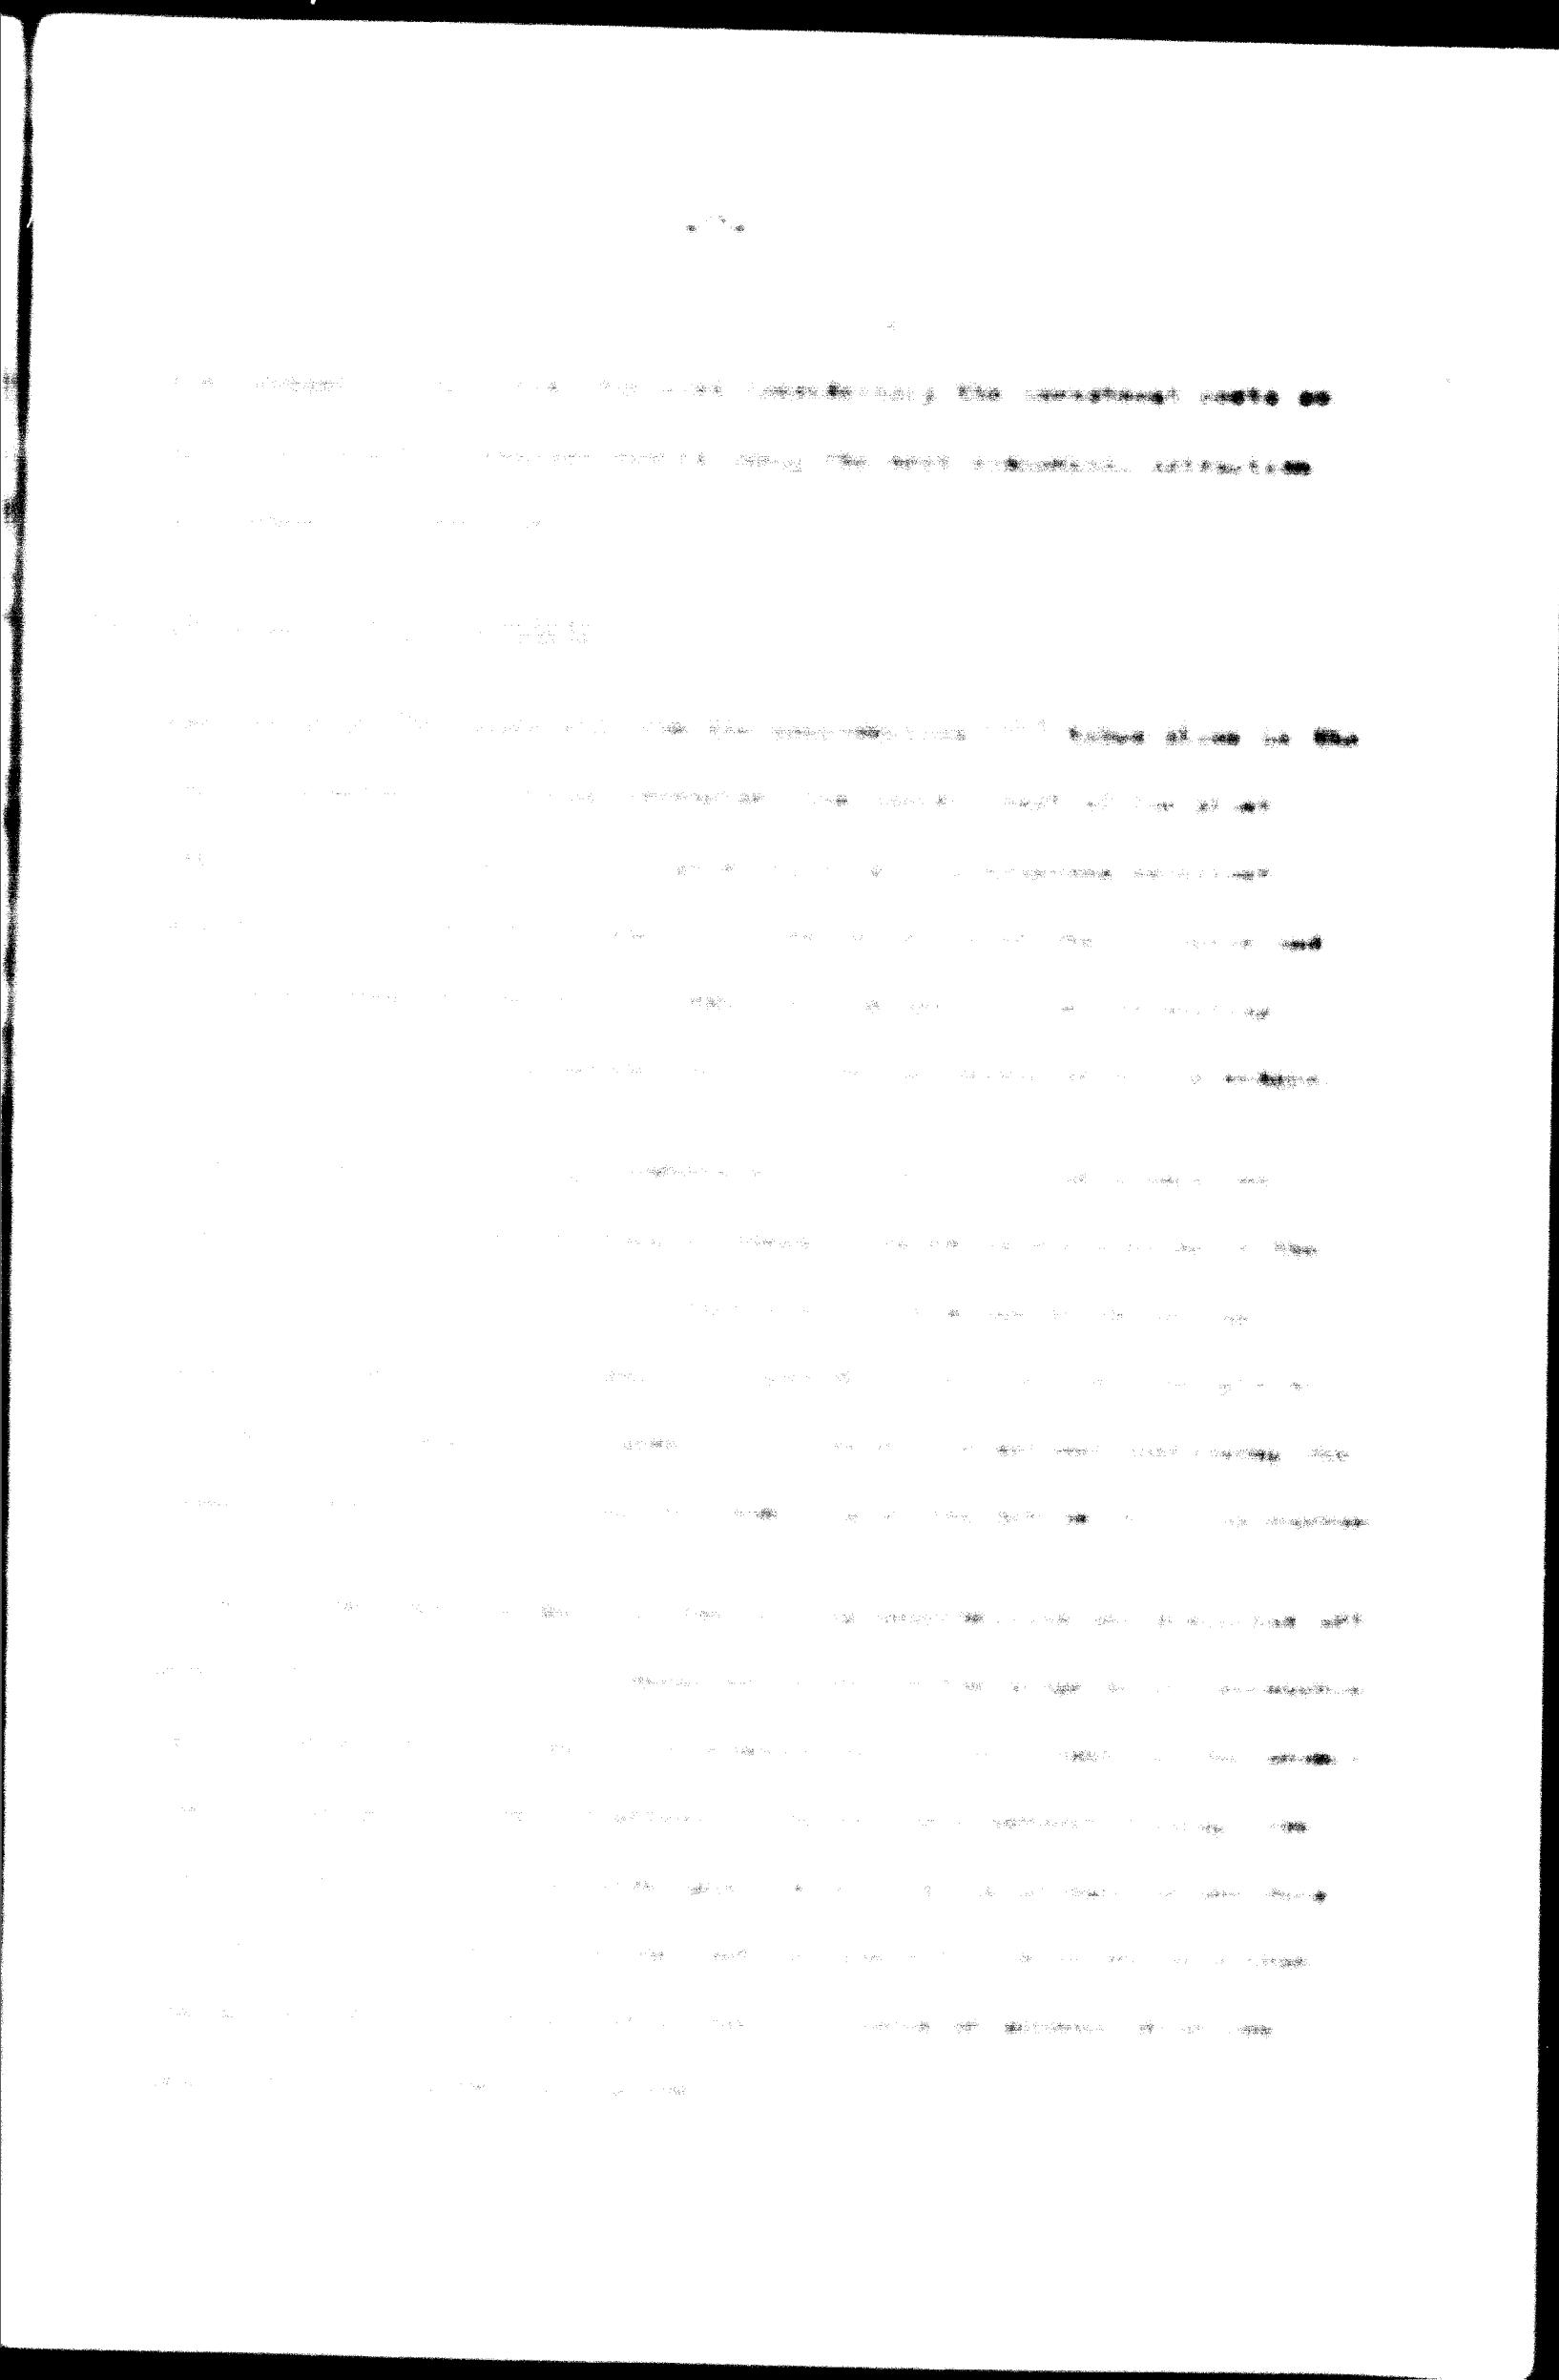

The pyrolysis products of naphtha, compared with coal-tar light oil rich in aromatics, contain a much larger proportion of ~~benzene~~ aromatics whose sharp separation from the aromatics by simple distillation would be uneconomical and impossible.

For this purpose Lurgi developed the 'Trosolver' process by means of which, with the aid of **TMP** ( $\gamma$ -methylpyrrolidone) as the solvent, aromatics of the highest purity are obtained in optimal yields and requiring the lowest power consumption.

The 'Trosolver' process was developed for the extraction of aromatics with **TMP/water** as the solvent mixture. Improvement of the selectivity of the solvent by the addition of water as the diluent, however, made it possible to produce aromatics in a high degree of purity. However, it was found that distillative separation of the solvent from the mixture by water distilling over azeotrope with the aromatics gave a relatively high steam consumption.

Further development of the process resulted in using glycol as the working component. The choice of the solvent mixture **TMP/glycol** not only reduced

Without further treatment being necessary, the pure aromatics can be separated from the nonaromatic components by distillation. The nonaromatics are collected at the top of the extractor column. They are then sent to the 2nd solvent scrubbing column with the water. The water, which still contains some solvent, is drawn off as overhead and sent to the 1st stripper column.

The overhead from the 2nd solvent separator is sent to a separator into water and hydrocarbons. After separation, the hydrocarbons flow

to the 1st solvent scrubber.

After separation, the water

based on a typical reformate or pyrolysis naphtha:

Steam (10-16 mm. gauge) 0.3 m.t.

An equivalent amount of heat in the form of fuel oil or fuel gas.

Feedstock (100°)

$20 \text{ m}^3$

Electricity

15 kWh

Dust (100°)

0.1 kg

The cost of consumption for the fractionating of 1 m.t. of pure aromatics

for a following simple distillation plant depends on the ratio in which

the two hydrocarbons are present in the feedstock; it is known from

experience that it is between 0.7 and 0.8 metric tons.

#### 2. Cost of consumption

To calculate the cost of economy, a calculation is given for a plant with an

operating time of approximately 2000 metric tons. The amount of aromatics

produced is 1000 metric tons/year (160 operating hours).

Electricity consumption

0.900 kWh

(0.8-2,250,000)

### Isophthalic dione

Recovery of benzene from coal tar light oils with 1-5% nonaromatics:

Yield: 95 - 98%  
Crystallization point: 5.45 - 5.5° C

Utilization per one metric ton of pure benzene:

Steam: 0.8 m.t.  
Coal tar oil: 40 m<sup>3</sup>  
Electricity: 7.6 kWh  
Solvent: 0.1 kg

### Isophthalic dione

Technol. of petrochemical progress, Vol. 4, 29/43 (1963)

2. Separation of benzene from aromatics extraction with solvent combination

Proceedings of the petrochem. congress, Vol. 4, 13/20 (1963)

### 13. Hydrodealkylation and dehydrogenation process

Hydrodealkylation in the absence of hydrogen has as its objective the splitting off of alkyl groups and even saturated rings, from aromatic hydrocarbons in order to obtain from substituted compounds of which there is an excess, the resulting lower substituted compound or preferably the unsubstituted basic compounds. Of the greatest importance today is the production of benzene from toluene and naphthalene from mono and dimethyl naphthalenes.

Work was already started by BISF in the early nineteen-forties on the catalytic dealkylation of benzene homologues (DEP 861.238, 1943). These studies which originally were directed especially toward the production of toluene (benzene benzene) from xylylene, were taken up again when a surplus of toluene was created through the petrochemical manufacture of benzene.

An industrial process was evolved which, in a first plant with an annual throughput of 120,000 metric tons toluene is to go on stream at Scholven-Chemie AG in the mid. of 1969. The process can also be employed for the dealkylation of naphthalene homologues; it is briefly described in the following; the example of the production of benzene from toluene.

### 13.1 Description of the process

Excess air from a waste reforming can be used to advantage as fresh gas for dealkylation instead of pure hydrogen. The fresh toluene together with the unreacted toluene and circulation gas is heated by heat exchange and in a pre-heater, and passed to the reaction zone which consists of two in-line reactors with regenerable catalyst. To limit a rise in temperature as a result of the high heat of reaction, quenchoil is added.

To remove the methane formed during dealkylation, part of the circulation gas, and in the case of reformer gas being used, the fresh gas itself, is conveyed to a hydrogen concentrating unit.

First the liquid reaction products are freed in a stabilizing column

at elevated pressure from the monomer(s) that boil at a lower temperature than benzene. It is also noted that at normal pressure, the left benzene is removed at the same initial volume. This suggests tolerance control of the reaction if a C<sub>8</sub> alkyl product, especially diphenyl, which is more difficult to remove. If the diphenyl fraction can be used, for example, as a motor oil, it can be recovered via the addition of benzene. The volume of this solution is possibly higher than the original, but by taking it out, plus, and operating costs of dealkylation are lowered somewhat.

### 13.2 Technical Data

#### a) Yield

(in the case of a toluene with 2% weight C<sub>8</sub>-aromatics and 0.5% by weight nonaromatics):

91.5% by weight pure benzene

1.5% by weight diphenyl fraction

#### b) Purity of benzene

Crystallization point	+	5.5° C
Bromine absorption	under	0.01 g/100 g
Potassium bromate	under	' ppm
Toluene content	under	' ppm

#### c) Stabilities and consumption of materials (for the dualylation of 1 molar ton toluene with combined air and water cooling including distillation)
