UNITED NATIONS INDUSTRIAL DEVELOPMENT ORGANIZATION
GENERAL ASSEMBLY

1977

1977
United Nations Industrial Development Organization
11, rue de la Fédération
1202 Geneva, Switzerland
Tel. 022 714 2111

All members are invited to send, by 15 October 1977, to the Secretary-General, United Nations Industrial Development Organization, 11, rue de la Fédération, 1202 Geneva, Switzerland, a report on the implementation of the recommendations of the Commission on World Employment, established by the General Assembly in 1976.

The Commission on World Employment was established by the General Assembly in 1976 to study the world employment situation and to report to the General Assembly on its findings and recommendations.

The Commission's first report, "World Employment: Trends and Prospects", was adopted by the General Assembly in 1977. It contains a detailed analysis of the world employment situation and a set of recommendations for action. The Commission's second report, "World Employment: Trends and Prospects", is being prepared and will be submitted to the General Assembly in 1978.

A sound investment policy should be based on careful forecasting and planning, to ensure that scarce capital resources be deployed so as to contribute maximum utility to the company's objectives of profitability and growth. A yardstick, with which to measure profitability to assess the attractiveness of investment proposals, therefore, of prime importance. Such yardsticks should enable a uniform consistent investment selection process, based on a reasonable screening and ranking of proposals submitted for the company's funds.

2. A break-even yardstick can be applied to a detailed analysis of income and expenditure for a given project over its life span. This should take into account - over the lifetime of the project - the market outlets and prices, variable and fixed costs in both the manufacturing and marketing spheres, as well as the expenditure on fixed and current assets. This analysis results in a detailed picture of the cash flows, both incoming and outgoing, associated with the project.
3. Several methods exist to derive the cash flows for a project over its lifetime yardstick for use in profitability assessment. Three of these, i.e. the pay-out time method, the financial statements method and the discounted cash flow method will be discussed in some detail. In particular, it will be studied to what extent these methods satisfy the basic requirements of applicability for screening and ranking purposes. The pay-out time indicates the length of time between the start of the project and the point where the cumulative cash flow breaks even with the cumulative expenditure. The shorter the pay-out period, the quicker the money at stake is earned back and the lower the risk to the company. It is thought, therefore, that as a guide to a ranking of proposals this method could have some use. However, to use profitability yardstick for screening purposes the method fails. This is because the full economic lifetime of the project is not taken into account. Cash flows after the break-even point is neglected.

The financial statements method overcomes part of these criticisms. Net income and net capital employed are related over the full economic life. Twenty year returns as well as a long run return over the lifetime of

the project can be computed, although the method has the advantage of close similarity to the books of the company so, in fact, no serious shortcomings still exist. The "time value of money" is not taken into account by this method.

It is only too easy to find even if a method which takes account of both full and net present values and the "time value of money". The "earning power" and "net present values" to be derived by this method can be used as indicators for screening and ranking purposes respectively.

4. For profitability assessment, however, can be regarded as complete without sensitivity analysis. The decision maker has to be aware of the weak points of the project. Is the profitability of the planned investment sensitive to increases in the costs of labor or a rise in prices of the bought-in base materials? What percentage rise in prices will reduce the profitability of the project below the acceptable minimum and how safely can we assume that this kind of prices will not occur? What will be the position if the capital cost of the project requires substantially more capital or if the start of commercial operations is seriously delayed? Questions of this character should all be considered in the analysis and enable management to regard each individual project in the right perspective.

We regret that some of the pages in the microfiche copy of this report may not be up to the proper legibility standards, even though the best possible copy was used for preparing the master fiche.

THE NEED FOR A YARDSTICK OF PROFITABILITY

The decision to invest a substantial sum of money in a new plant is one of the most important and, therefore, one of the most challenging decisions financial management has to make. In investing capital in new productive facilities, a company commits itself for many years to a specific range of products and markets. In particular in the petrochemical industry facilities are designed for making a few specific products, and the possibilities of expansion afterwards are very limited. Once the money has been spent the decision to invest has either been irrevocable. The challenge to management, therefore, is to control the future with its risks and uncertainties.

Although the investments in new plants can be based upon a great variety of arguments, but they all should have in common the principle that the investments will contribute to the ultimate objectives of the enterprise. It seems useful, therefore, before going into the use of investment yardsticks, to have a close look at the objectives of an industrial enterprise.

In the modern concept of industrial activity, expressed in the new economic terms, the function of the enterprise is to create wealth and wellbeing for all parties involved in the economic process, suppliers and customers, creditors as well as the government. It can be seen as a conglomerate of interrelated economic activities which has its own and unique contribution to the functioning of the company and, in addition, to derive from the company. As long as the company is solvent, its obligations and claims on the outside world are a direct result of the company's activities. It is not of course necessary to say one of them is the company's liability to assume that the result of its activities is the creation of wealth and business activities.

However, this broad and overall objective is not an immediately measurable one. It needs translation into clear numerical terms which can serve as a guide for economic decisions, including decisions in the area of investment for the industrial enterprise and its profitability.

Although secondary to the profit interests, but growing competition as well as the need for new and better technological progress and higher efficiency in production, including the utilisation of manpower, forces the company to keep pace with these developments, the economic position will be affected, its margin between cost and price will narrow and in the end its continuity will be endangered.

If the company is forced to invest in new plant to enter new markets, it must remain competitive and retain, if possible, its market share for existing products.

The funds required for investment in new plant and also for research and development will largely have to be generated by the business itself. The company, therefore, has to watch permanently its level of cash generation, or to use the more general term, its profitability. This not only applies to its present activities, but in particular also to the additional activities resulting from new investments. It is for this reason that the expected profit potential of a new project is a major point of consideration for management when taking a decision on investment proposals.

At the same time, it will be appreciated that a company's investment program will not only embrace projects which will in a direct way generate additional income or produce savings on cost, as is the case with successful manufacturing projects. New office buildings and overhead facilities at the plant's site for example will have to be assessed on an urgency or social necessity basis, instead of on a basis of profitability. It is evident that a company's future position with respect to earnings and growth will be influenced more favourably, if the profit potential of a new project is higher.

There is, therefore, a need to measure profitability. In other words, a profitability yardstick is required with which to assess the attractiveness of new investments.

Such a yardstick should serve two purposes :

- (a) It should enable projects to be selected which look sufficiently profitable and well prepared, to be rejected which do not appear to be sufficiently attractive to carry out. It should, therefore, lead to a correct screening of proposals for investment, so that projects which do not meet a minimum requirement of profitability can be dropped.
- (b) It should provide a reliable indication as to which of various alternative proposals for investment is the more attractive, keeping in mind that funds available for investment are limited. In other words, a correct ranking of investment proposals, competing for the company's funds, should be achieved.

Two conclusions immediately follow from the above :

- (i) It is important that within a company whose management has to decide on many possibilities for investment, the assessment of project profitability should always follow the same lines of approach, i.e. a standardised method should be used.
- (ii) It is a vital and primary task for a business enterprise to decide what the minimum acceptable profitability level for its new projects should be.

without wishing to go into detail with regard to the latter problem, since this would fall outside the scope of this paper, a few brief remarks on the subject are felt to be of interest.

Management may wish to see their company grow rapidly. However, too many new projects will tend to depress the future earnings of the company, as it will always take a number of years before such new projects will start to contribute adequately to the company's profits. Financing may then become a problem, since it will prove difficult to attract new finance into a company with a declining profit record in relation to its capital employed.

The other extreme would be a low growth rate, leading to the possibility of high dividends, since a small part only of the profits would be required for re-investment. Such a policy may be dangerous, however, since the company's competitors would continue to grow and after a period the company would find its position seriously weakened. In this case profits will diminish in the long run as no new products have added or modern plant installed.

Between these two extremes a balanced position should be sought. In reaching the best way of tackling the problem might be to draw a financial forecast of the existing business and to determine at this a varying volume of investment with a view to a degree of profitability, taking into account such elements as requirements of financing, dividend policy, etc. From such a forecast a firm requirement as to the profitability of new projects might then be derived.

II. BASIC ELEMENTS OF PROFITABILITY CALCULATION

The life of the business entrepreneur, when fitting out ships for a business, is a very simple way. Although a number of years may be required to take the odds, as in case of business, the odds are not substantial. At that time the basic element is profit, it was either going bankrupt or becoming an entrepreneur. The continuity of the enterprise was by no means a foregone conclusion, nor apparently - was it a foregone conclusion of the entrepreneur.

It is clear that the entrepreneur today, being far more concerned about the future position of his company, will approach his investment in a more sophisticated way. From his start of operations he will receive an assessment, as well as can be done, of the various uncertainties which are inherent in estimating the cost of the project, the capital cost of the project, the cost of operating the plant, the cost of raw materials, the proceeds to be expected from selling the product, etc. To judge the merits of a new project, the basic elements required to put in the overall picture are in principle

always the same. However, they will have to be worked out in more or less detail depending on the yardstick to be applied. These elements are the following.

1. The available market for the product

An assessment will have to be made of the size and growth potential of the market for the product(s) in question and an estimate must be made of the market share that can be achieved by the company. Furthermore, also the price at which the product(s) can be sold will have to be considered carefully, both for the home and export market. This is, no doubt one of the most difficult jobs in predicting the future. Use will be made of the price history of the product (or of a substitute product for similar use in case the product is a completely new one) but it is difficult to estimate what the reaction of competitors might be, whether they as well plan for extension and consequently whether the danger of a substantial overcapacity developing may exist. In addition to the price also the costs of marketing the products should be determined, including the cost of the sales department, cost of delivery, packing, storage and handling, and cost of packages.

A continuous analysis of the market and an extrapolation into the future by people who are well aware of its peculiarities looks the best way to obtain a balanced forecast, which takes account of all upward and downward pressures. It should be realised, however, that even so the actual price development may be substantially different, e.g. the development of a new process or a competitive product not foreseen at the time may cause a price drop which makes the forecast invalid. Nevertheless, in most cases developments will not be so dramatic and it is part and parcel of business life to accept this type of risk.

2. Capital cost of the new plant

Having determined the volume of product that can be sold, the capacity of the plant to be considered can now be set and its capital cost estimated. Care should be taken that the capital cost so determined should, indeed, embrace all the facilities which will have to be constructed to realise the project. Apart from the processing units proper, it should also include the cost of such items as site preparation, social amenities, access roads, sewer system, storage and handling facilities, flare system, supply of utilities, measures to settle water and air pollution and so on.

In an early stage of development approximate figures can be given for the several parts of the project, by scaling from previously built plants and by applying overall percentages for off-plot items. However, the accuracy will be rather low and a technical study in detail will be required in further developing the project to firm-up the capital costs.

By doing a preliminary and an electrical estimate will have to define the scope of the project. It may be the case that in sufficient detail to enable a more accurate estimate to prepare a preliminary estimate. All the above mentioned factors experience and have to be taken into account. The estimate should be made with the help of the people who have the necessary knowledge and who keep their hands on the project. A detailed analysis of the general cost of production should be made. The estimate prepared will be a very useful basis for the investment decision. It will also be very useful for expansion of the plant and for other reasons.

Cost of production

From the design and/or from the records of actual operation of plants of similar type, yield and consumption figures will be available which can be converted into cost per unit of product. If the cost of the basic input materials are known. With regard to the latter there may be a good reason to approach the early stage potential suppliers of those materials which give an important bearing on the total cost of the product. Fixed costs, covering cost of operating labour, cost of maintenance and overhead, can often be estimated with reasonable accuracy by using the actual records of plants of similar nature and by seeking the advice from staff who have a good experience in the operation and maintenance of chemical plants. Overhead costs are estimated on a statistical basis. In case of doubt, it is advised by making a detailed analysis of the many items which will form the total overhead needed.

With the above data available, it is possible to apply a simple profitability yardstick which admittedly is not much used for final decisions but seems worth mentioning as a short-cut for a quick initial appraisal.

By deducting the cut-off-point expenses of production and of marketing from the proceeds, the annual cash surplus at full load and before tax can be estimated. This cash surplus can then be divided by the fixed capital involved in the project to obtain a "rate of pay-out".

| | | |
|-----------|------------------------|-------------------|
| Example : | Capital | 100 |
| | Proceeds | 60 (at full load) |
| | Manufacturing Expenses | 45 |
| | Marketing Expenses | 10 |

$$\text{Rate of Pay-out} = \frac{60 - 45 - 10}{100} = 25\% \text{ per year}$$

The release of this could indicate that the project will be started next spring and that the project will be completed by the end of the year.

This information is being provided to you for your information. In part, this information is being provided to you for your information of the project and the progress of the project.

Project Status Report - 10/15/78

The project is currently in the planning stage. The project will be started next spring and the project will be completed by the end of the year.

Project Description

One of the major objectives of the project is to develop a new project which will be completed by the end of the year. The project will be started next spring and the project will be completed by the end of the year.

The project will be started next spring and the project will be completed by the end of the year.

Project Objectives

There are several objectives of the project. The objectives of the project are to develop a new project which will be completed by the end of the year. The project will be started next spring and the project will be completed by the end of the year.

Project Budget

Substantial resources will be required for the project. The project will be started next spring and the project will be completed by the end of the year.

Further information is being provided to you for your information. In part, this information is being provided to you for your information of the project and the progress of the project.

The profitability, theoretically, should be estimated for the full lifetime of the project. However, this lifetime is rarely known exactly. In most cases it can only be set in an arbitrary way. Even though it probably has a definite lifetime or, say, a wear-out time, it may become obsolete long before as a result of technological progress appearing on the market, an improvement being introduced or a change in demand, rendering it obsolete and useless.

It is, therefore, practically impossible to estimate the profitability to a period of time. In fact, in these cases there are clear reasons to assume that the project will have a longer lifetime. In this case, the profitability of a project or investment may be compared to a normal rate of interest.

To assess the profitability of a proposed investment several methods are available. In the present paper, the following method will be used and explained:

- (a) The initial investment
- (b) The annual cash flow
- (c) The discount rate

When comparing the advantages and disadvantages of the various years of the project, it is necessary to keep the two sides of the account in balance. We have:

- (a) The initial investment, which is a negative value for the project.
- (b) The annual cash flow, which is a positive value for the project.

To find the profitability of the project, the various values must be discounted to their present value. The discount rate is the rate of interest that the investor would expect to receive if he had invested the money in a similar project. The discount rate is usually the rate of interest on government bonds. The present value of the project is the sum of the present values of the cash flows minus the initial investment.

The present value of the project is the sum of the present values of the cash flows minus the initial investment. The present value of the cash flows is the sum of the present values of the cash flows. The present value of the initial investment is the initial investment divided by (1 + discount rate)^0.

Finally, the profitability of the project is the present value of the project divided by the initial investment. The profitability of the project is the present value of the project divided by the initial investment.

Full details on these two projects A and B are tabulated in appendices II and III respectively

From these tables it will be seen that project A requires an outlay of £ 500,000 on fixed assets, whereas modifications of the existing development plant in project B are estimated at £ 125,000 only. For the sake of the calculation equal construction periods have been assumed.

The larger plant, despite the low incremental capital cost to realise the extra unit, will be more efficient when operating at full capacity, which can be seen from the following :

| | <u>Project A 15,000 t/a</u> | | <u>Project B 5,000 t/a</u> | |
|---------------|-----------------------------|------|----------------------------|------|
| | in £/t | | in £/t | |
| netback | | 40.0 | | 52.8 |
| variable cost | 6.0 | | 10.0 | |
| fixed cost | 15.0 | | 15.0 | |
| depreciation | 9.7 | 26.7 | 5.0 | 30.0 |
| gross profit | | 14.6 | | 22.8 |

However, the higher manufacturing costs of case B are more than compensated by the higher netback obtainable, so that on balance profit before tax in case B is some £ 7.8/t higher.

Let us now consider how the profitability characteristics selected for further discussion stand up with regard to the screening and ranking questions. A and B are both projects which are profitable investment and, of so, which investment is to be preferred.

1. The pay-back time method

The pay-back time (PBT) is often referred to as the "pay-back criterion", indicates the time lapse between the start of the project and the time in time where the cumulative cash inflow breaks even with the cumulative expenditure. A graphical presentation of the cumulative cashflows of projects A and B is shown in appendix IV.

It appears from these graphs that the pay-back times are almost equal, say 4.5 years from the start of operations, or 5 years when building time is taken into account.

The overall conclusion of the ranking exercise is to be preferred on the basis of pay-back time is difficult to answer. The higher fixed cost of project A, together with the higher depreciation, recorded in the early years of the project, together with the earlier expenditure on building time, are all factors which, in the absence of great fluctuations in the price of the product, or significant changes in the market, neutralisers, might favour project B. However, if the market should be put at risk

It is especially under conditions of great uncertainty that the pay-out criterion can serve as an indication for ranking purposes, in so far that the shorter pay-out time will then be preferred in case capital outlays will be more or less the same. This policy will tend to maximize the risks to the company. Equally, under such conditions, in case of identical pay-out times, the less capital for the project will be preferred.

One may conclude, therefore, that under special conditions, the pay-out time should be given some indication as to the order of preference of projects. However, if a reasonably reliable estimate as to the future shape of the cash flow is made and if no severe uncertainty exists, the rather simple to give an indication as to the project which is preferred.

This bears relation to the well known shortcoming of the method in that the pay-out time is calculated on a limited part only of the whole project life. It neglects the impact of cash income, realized after the break-even point. It fails, in particular, at the point of expressing the relationship between total cash flows and total cash outlays. A more complete estimate of a project's profitability, however, is not a true profitability yardstick, as it does not take into account all how profitability of the project developed in the future and this is what one would like to know in order to make decisions. It may be generally concluded, therefore, that the pay-out time method is not so restrictive as it is often held to be in investment decisions. Other and better procedures are required.

3. The Profitability Index Method

This method is also referred to as the cost-benefit method. Company executives are usually to find it in their annual reports in which usually are listed investments and the cash flows are shown. The P.I. method expresses the results for a particular project in very simple terms with the implicit assumption that the project is profitable if the benefit or cash flow is greater than the results of the investment. The benefit flows are given by year and the cash flows are the total cash outlay. The P.I. is then calculated as the ratio of the benefit to the cash outlay. When dividing the total cash flow by the total cash outlay, the result of the P.I. method is obtained. Furthermore, the average of the P.I. values for all projects of the firm or the project will be the P.I. of the firm.

By using the P.I. method, the P.I. of a project which takes only a short time to complete is not taken into account. In the case of a firm which has a large number of projects, both currently and in the future, the P.I. method for projects A and B respectively. Since the P.I. is based on the fixed assets

decreases from year to year because of depreciation, whilst usually the book profit increases after the early years when the plant gets more fully loaded, the series of return figures obtained shows a tendency to increase. The method certainly has its merits. It takes into account the whole lifetime of the plant and, by superimposing the project on a forecast of the existing business of the company, a picture can be obtained of the company's book result and balance sheets with and without the project. This may be of interest particularly in cases where the project is of large size as compared to the existing business of the company concerned. Although the project in itself may be sufficiently attractive to pay wages in the overall company during a number of years in such a way that it nevertheless may be felt to be rejectable.

As an indication of the profitability of the employed capital and, therefore, as a tool for screening, this method certainly can be very useful. However, the usefulness of the method as a tool for ranking has to be considered. To this end a graphical presentation of the annual book returns and the average cumulative book returns is shown in Appendix VII.

It can be seen that both the series of annual returns and those of the average cumulative returns show an identical picture. Initially, B appears the better of the two alternatives as less capital has to be spent. However, during a number of interim years the order of preference seems to be reversed, whereas over the entire period, B again appears to be a better proposition than A.

The choice between the alternatives when B is difficult to make. The reason is that it depends on the time period we consider which alternative we would prefer. If one regards initial earnings to be of more importance than later ones, one would certainly make the choice in favour of A. In case one would like to stress the earnings at full capacity reached at a later stage, or would prefer to take the whole life of the plant into consideration, alternative B would be the most attractive. However, this aspect of timing is not adequately taken into account by the method. This can easily be seen from the following example. Projects X and Y have identical average net employed capitals over the period considered. Net income, however, although in total the same, differs as to the periods in which it is earned.

| Years | 1 | 2 | 3 | 4 | 5 |
|--------------------------------|-------|-------|-------|-------|------|
| <u>Project X</u> | | | | | |
| Average net capital employed | 450 | 350 | 250 | 150 | 50 |
| Net income | - | 50 | 100 | 150 | 200 |
| Book Return per annum | - | 14.3% | 40% | 100% | 400% |
| Average cumulative book return | - | 6.5% | 24.3% | 25% | 40% |
| <u>Project Y</u> | | | | | |
| Average net capital employed | 450 | 350 | 250 | 150 | 50 |
| Net income | 200 | 150 | 100 | 50 | - |
| Book Return per annum | 44.4% | 42.9% | 40% | 33% | - |
| Average cumulative | 44.4% | 43.3% | 42.3% | 41.7% | 40% |

The average cumulative rate of return measured over the whole lifetime of both projects is equal to 40%, indicating that, although individual annual values differ considerably, both proposals in the long run are equally attractive. Nevertheless, a company would prefer project Y because of its faster earnings potential.

This financial statements method fails to take into consideration the so-called 'time value of money'. The entrepreneur is not indifferent to the fact whether he receives £ 10 a year earlier or later. He will always show a preference for the earlier when it relates to a receipt of cash and for the later when an outlay of money is under discussion. The reason for this is the opportunity to re-invest money and to realise extra income which otherwise would be foregone.

If we introduce the 'time value of money' -concept it will be clear that the financial statements method has another weak point. It is not only net earnings which are generated by a project but depreciation was well. In other words, the cash flow which comprises net income plus depreciation is the real basis to be considered if one introduces the opportunity to re-invest money.

It may be concluded, therefore, that a method in order to be a sound device for both screening and ranking, should meet two requirements :

- it should take account of the cash flows during the full economic life of a project.
- it should take account of the "time value of money"

It will be seen in the following, that the discounted cash flow method meets both these requirements

3. The discounted cash flow method

This method is based on the very concept of the time value of money. A few simple examples will assist in demonstrating, how this concept can be applied in profitability studies

Assume that for a given company each additional pound (£) tied-up in the business should yield a profitability of 10% per year. One may then conclude that £1 received or spent today will be equivalent to £1.10 one year from now or to £1.21 two years from now etc. Similarly, the £1 received or spent today would have been equivalent to £0.91 one year before or to £0.83 two years earlier etc.

It will be clear that the application of this principle makes it possible to express in monetary terms the distance in time, which separates any element in the cash flow, associated with a project, from any other cash flow element. In the case of a number of cash flow figures this is conveniently done by reducing all cash flows to a chosen key date by multiplying with the appropriate discount factor. The summation of these reduced cash flow elements is usually termed the present value or present day value of the cash flow per that date.

Two examples may elucidate this way of approach :

- a) A company has to solve a transport problem. It can either buy its own road tanker or it can contract out to a transportation firm. In the first alternative, it will have to invest in a road tanker, which is assumed to have a three year life. It is also known that the company can achieve an 8% minimum return on its investments. An analysis of the two alternatives shows the following annual cost comparison:

| | <u>Operating cost</u> <u>per year</u> | <u>Contracting</u> <u>cost</u> | <u>Discount factor</u> <u>10% p.a. per annum</u> |
|------|--|-----------------------------------|---|
| 1970 | £ 10,000 | . | 0.909 |
| 1971 | 3,000 | £ 7,000 | 0.826 |
| 1972 | 3,000 | 7,000 | 0.751 |
| 1973 | 3,000 | 7,000 | 0.676 |

The annual cash-outflows are now all discounted to 1st January, 1970, using the discount factors indicated. Upon adding, the following present value has been obtained:

£ 27,150 £ 20,831

The company might choose to accept the contractor's bid. It will be seen that the problem set here is a ranking problem.

- c) The same company has a piece of land from one of its plants, which still acts as a valuable asset. After recovery this could be converted to an open area, but an additional column would have to be added, costing £ 10,000. Its lifetime will be 10 years. Other data needed for determining costs and the effect of taxation - the latter being 50% - is £ 1,000 each year. The cash flow picture, upon including the column, would be as follows:

| | | |
|---------|---------------|------------|
| 1970 | investment | £ (10,000) |
| 1971/80 | annual saving | £ 1,000 |

Present value calculations are as follows:

PV at 10% p.a. 1-1-70 equals £ (9,700) and PV equals zero per 1-1-1970 at a discount rate of 10%

The company decides to reject the proposal and not to recover the material from the piece of land. The problem tackled in this case was a screening problem.

Conversely, for a given set of cash inflows, associated with a new project, a discount rate can be found for which the present value of the project will amount to zero. In other words, the present value of the cash outflows - in the early years - will be equal to the present value of the cash inflows - usually in the later years - when discounted at that rate.

The discount rate which achieves this is called the internal rate of return of the capital project.

Quite generally, therefore, the essence of the discounted cash flow method can be expressed as follows :

$$\sum_{n=0}^{\infty} \frac{a_n \text{ (cash in-flow) year } n}{(1+i)^n} - \sum_{n=0}^{\infty} \frac{b_n \text{ (cash out-flow) year } n}{(1+i)^n}$$

When equated to zero and solved for i , the earning power of a project will result, which provides a yardstick for screening purposes

The numerical value obtained for the polynomial for a given value of i , represents the present value of the cash flow in question for a discount rate of i . The present values are useful for ranking purposes

The above considerations will now be applied to the projects A and B, already cited in the foregoing. It will be assumed that the cut-off point for profitability has been set for the company at an earning power of 8%.

The following table recapitulates the cash flows for both projects (see Appendixes II and III) :

| Year | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|----------------------|-------|-------|----|-----|-----|-----|-----|
| Cash flow, project A | (200) | (115) | 25 | 155 | 155 | 205 | 205 |
| Cash flow, project B | (50) | (75) | 5 | 25 | 40 | 60 | 62 |

Upon calculating the earning powers, it is found that :

earning power, project A equals 11.5%
 project B equals 13.0%

The conclusion to be drawn from these results is simply that both projects A and B meet the minimum standard of an earning power of 8%. It follows that both projects are worthy to be carried out, although B appears to be better than A. Since, however, as was assumed from the beginning, the proposal is not mutually exclusive the choice becomes more complicated

Calculation of the present values for a discount rate of 8% reveals the following :

8% Present Value for Project A \$ 55,000
 8% Present Value for Project B 25,000

It is evident, that a positive present value means that the earning power of the proposal is higher than the cut-off rate. The present values obtained confirm, therefore, that both projects A and B meet the minimum requirements. However, the ranking order has been reversed. On the basis of present values project A appears to be preferred over B, whereas according to the earning power outcomes project B looked to be the most attractive proposition. The optimum choice is still not clear.

It will be understandable, however, that the ranking choice should not be based on the individual earning power outcomes, because the capitals involved are different.

If one faces the choice between earning 12% on a small investment of £ 125,000 or 11.5% on a higher capital of £ 515,000 it may very well be that the last proposition is the more attractive. This will be true, if the incremental investment of £ 390,000 will generate enough incremental cash to justify the extra expenditure. Therefore, an incremental cash flow should be calculated and the earning power for this cash flow determined.

Incremental cash flow of project A over project B

| Year | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|----------------|-------|-------|----|-----|-----|-----|-----|
| Cashflow A - B | (150) | (240) | 16 | 150 | 155 | 145 | 133 |

The earning power associated with this cash flow is calculated to be 10.1%. The conclusion to be drawn is that indeed, proposal A, although having a somewhat lower EP than B, is the most attractive proposal since the additional capital to be spent still shows a profitability which is above the minimum required level. It will be noted that this result is in line with the present value results which already indicated project A to be the most attractive in spite of its higher expenditure.

This method can be universally applied to any type of cash flow, associated with an investment proposal in industry. In particular, the DCF method can deal with ease and elegance with the common problem of successive investments in a business, whether in the case of step-wise expansion or for instance, by integrating backwards into base material production at a certain stage. The DCF method may rightly be termed a powerful tool in the solution of economic problems encountered in industry.

4. Worked out case study

To show the DCF method in its practical application, a fully worked out example for the profitability assessment of an imaginary polypropylene project is shown in Appendices VIII-1 to VIII-5. It should be noted that the levels of costs and prices, used in this example, are not necessarily applicable under present conditions. This is, however, irrelevant for the present purposes. The appendices show in some detail the data which are to be collected, and the calculations to be performed to arrive at the cash flow schedule with the project. The following elements are worked out in the appendices:

- sales forecasts and production programming, having regard to the build-up of stocks in the initial years of production;
- selling prices, marketing costs and netbacks to plant;
- the estimated capital cost of the production plant;
- the manufacturing cost estimate;
- the overall capital requirements of the project;
- the calculation of the tax, payable by the company and finally, the resulting cash flows.

The parameters characterizing the project can now be calculated and are found to be as follows:

| | |
|-------------------------------|--------------|
| Discounting factor | 10.5% |
| Sp. investment present value | \$ 1,475,000 |
| DCF of expected present value | \$ 2,000,000 |
| Pay-out time | 3.6 years |

In the table appended to No. IX, the cash flows generated by the project, both annual and on a cumulative basis, are shown graphically.

Graphs of this nature enable an appraisal to be made of the finance requirements of a project before it reaches the productive stage, when it starts to contribute to the company's finances.

IV UNCERTAINTY AND RISK

Especially for new products if processes are unproven and, consequently, risks will be considerable. Market research and process development departments will have given their best opinions, pilot plants may have performed well and a limited marketing may have proved good and may be accepted.

Nevertheless, a great many uncertainties and risk factors will still exist. Difficulties may be encountered regarding the construction of the plant, leading to higher capital expenditure or a delay in completion of the construction work itself. The operating efficiency, particularly in initial operation, may be disappointing and lower yields on basic materials may be achieved, leading to higher than estimated manufacturing costs. A competitive product may appear on the scene, resulting in a slower than anticipated market build-up or lower selling prices for the product from the new plant. Therefore, as corollaries to the main profitability calculation, the sensitivity of the project to a number of adverse factors, which may or may not occur, should be determined. An analysis of these risks and sensitivities, showing their impact on the project's attractiveness, should complete the evaluation of new projects. This sensitivity analysis adds more dimensions to the evaluation and will assist towards a balanced appraisal of new investment proposals.
