(Received 31 October 2011; revised manuscript received 9 April 2012)

A kinetic model is proposed for simulating the trajectory of a single milling ball in a planetary ball mill, and a model is also proposed for simulating the local energy transfer during the ball milling process under no-slip condition. Based on the kinematics of ball motion, the collision frequency and power are described and the normal impact forces and effective power are derived from analyses of collision geometry. The Hertzian impact theory is applied to formulate these models, after having established some relationships among geometric, dynamic, and thermophysical parameters. Simulation is carried out based on two models, and the effects of the rotation velocity of the planetary disk $\Omega$ and the vial-to-disk speed ratio $\omega/\Omega$ on other kinetic parameters have been investigated. As a result, the optimal ratio $\omega/\Omega$ to obtain high impact energy in the standard operating condition at $\Omega = 800$ rpm is estimated, which is equal to 1.15.

Keywords: ball motion, energy transfer, kinetic model, milling ball

1. Introduction

Several previous studies have reviewed the development of kinetic models related to mechanical milling. Many attempts[1−13] have been made to simulate the kinetics of the milling process in terms of ball velocity, frequency of impact, and kinetic energy transferred to the powder during milling.[1−13] However, the physical and chemical changes induced by the violent impact and accompanying shear forces during the milling are still puzzling. A variety of powder coalescence and fragmentation mechanisms play great roles in the milling process. The conversion efficiency of the total power, generated by an impact, to effective power transferred from the ball to the powder during an impact and the impact frequency are the two important parameters determining the efficiency of the milling process.[1] Recent experimental researches concentrate on both the sway ball mill and the planetary ball mill: the impact velocity of the milling ball and the temperature of the vial can be experimentally monitored during milling, and the mechanisms of energy conversion can thus be studied.

Several models for describing the kinetics and trajectory of the milling ball have been proposed by Burgio,[5] Magini,[6] Abdellaoui,[9] Dallimore,[12] and Chattopadhyay,[13] so that both the velocity of the milling ball and its energy transfer can be calculated. Zidane et al.[14] have established an equation describing the contact temperature at the impact point as a function of other parameters. A back-propagation (BP) neural network technique was applied to predict the properties of milling powders for various milling parameters and has proved suitable.[16]

Davis et al.[17] have tested the impact velocity of the milling ball in a sway SPEX mill, and obtained the results of 19 m/s (maximal) and 6 m/s (average) with the impact energy mainly ranging from $10^{-3}$ to $10^{-2}$ J. By virtue of the geometry simplified model, Maurice and Courtney[14] predicted that the sway frequency of the SPEX mill was 1020 times per minute, and the average impact velocity was 3.9 m/s.

las et al.\textsuperscript{[18]} and Loiselle et al.\textsuperscript{[19]} used calorimetry to test the impact speed of the SPEX mill, and obtained the results of 3.8 and 3.6 m/s, respectively. Contact temperature increases with the impact velocity in the experiment conducted by Zidane et al.\textsuperscript{[14]}

The operating principle in the planetary ball mill is as follows: either four or two vials are settled symmetrically on a planetary disk. Each vial rotates around its center \( C \), as well as around the origin \( O \) located at the center of planetary disk in the opposite direction (Fig. 1); such movement confers high kinetic energy to the ball. The centrifugal force induced by rotation drives the ball to move along the vial wall, while strong friction, induced by the speed differences between the vial wall and ball, acts on the samples to be milled. As the driving speed increases, the Coriolis force (rotation bias force) forces the milling ball to leave its position from the vial wall. Subsequently, the ball starts to move inside the vial, hit the samples against the moving vial, and thus liberate massive impact momentum. The combination of impact momentum and friction force confers a high grinding capacity to the planetary ball mill.

\begin{figure}[h]
\centering
\includegraphics[width=0.4\textwidth]{fig1.png}
\caption{Schematic drawing of the operating principle of the planetary ball mill.}
\end{figure}

2. A kinetic model for the trajectory of a single milling ball in a planetary ball mill

As shown in Fig. 2, a kinetic model is established in the Cartesian reference space on the basis of the model established by Chattopadhyay et al.\textsuperscript{[13]} The kinematic analysis of ball motion is presented here in terms of a spherical Cartesian reference frame with its origin \( (O) \) located at the center of the planetary disk.\textsuperscript{[13]} Here, the distance between the origin \( O \) and center \( C \) of the vial is \( r_d \), and \( r_v \) is the radius of the vial. The rotational speed of the disk is \( \Omega \) in the anticlockwise (or normal) direction and determined by the rotational speed of the line \( OC \). In accordance with the planetary motion of the mill, the rotational speed of the vial in the clockwise direction relative to the line \( OC \) is \( \omega \). Here, \( P_0(x_0, y_0) \) is a point on the vial surface lying on the line \( OC \), which is taken as the initial point of the ball motion.

\begin{figure}[h]
\centering
\includegraphics[width=0.4\textwidth]{fig2.png}
\caption{Motion trajectory of a ball, showing the successive positions of the ball on the vial surface at the points of initiation \((t = 0)\), detachment \((t = t_1)\), and collision \((t = t_1 + t_2)\).}
\end{figure}

Resolution of the centrifugal force, originating from the rotation of the vial and disk (\( F_v \) and \( F_d \)) along the direction \( P_tC_0 \), yields the net reaction force (\( F_c \)) acting on the ball (Fig. 2). At the point of detachment (i.e., at \( t = t_1 \)), the resultant reaction on the ball is reduced to zero (i.e., \( F_c = 0 \)), and thus the ball leaves from the wall of the vial. The motion of the ball continues for an interval \( t_2 \) without acceleration until it collides with the vial surface (Fig. 2), thus entering the next cycle of its movement.

To simplify the analysis, the following hypotheses for the kinetic system are proposed:

(1) The motion system in a vial, virtually involving a number of balls, is considered as the linear cumulative of a single ball motion. In other words, the balls are assumed not to interfere with each other’s motion, and hence the kinematics of a single ball represents the overall process.\textsuperscript{[5,9]}

078201-2
(2) The equations proposed do not take into account the slip factor, really existing during the mechanical milling process. Nevertheless, they make a good approach to prove that the injected shock power is responsible for the ball milled end product. [9] The ball adherent to the peripheral points $P_0(x_0, y_0)$ or $P_2(x_2, y_2)$ moves without rolling or sliding on the inner wall.

(3) After a succession of hits with the inner wall, the ball adheres to the inner wall, and then is accelerated by the vial again, ready for the next flight.

(4) The ball is regarded as a mass point. [9]

The time period from 0 to $t_1$ corresponds to the interval during which the ball moves from position $P_0(x_0, y_0)$ to $P_1(x_1, y_1)$. At any instant $t$ during this period, the position vectors $x$ and $y$ of the ball can be expressed as [13]

$$x = r_d \cos \Omega t + r_v \cos(\Omega - \omega)t,$$

$$y = r_d \sin \Omega t + r_v \sin(\Omega - \omega)t.$$  \hspace{1cm} (1)

Thus, the respective velocity components in the $x$ and $y$ directions, i.e. $v_x$ and $v_y$, can be obtained

$$v_x = \frac{dx}{dt} = -\Omega r_d \sin \Omega t - (\Omega - \omega)r_v \sin(\Omega - \omega)t,$$

$$v_y = \frac{dy}{dt} = \Omega r_d \cos \Omega t + (\Omega - \omega)r_v \cos(\Omega - \omega)t.$$  \hspace{1cm} (2)

The physical forces applied to the ball are its weight (gravitational action) and the vial reaction. The ball weight is negligible as compared with the vial reaction. [9] Based on the fundamental dynamic principal, at $t = t_1$, the centrifugal force $F_c$ acting on the ball can be obtained, which originates from the rotation of the vial and disk ($F_c$ and $F_d$) and points to the axis of the vial:

$$F_c = F_c - \cos \gamma F_d,$$  \hspace{1cm} (5)

$$F_d = mr_d \Omega^2,$$  \hspace{1cm} (6)

$$F_v = mr_v \omega^2,$$  \hspace{1cm} (7)

$$\gamma = \pi - \phi.$$  \hspace{1cm} (8)

Substitute Eqs. (6)–(8) into Eq. (5), we obtain

$$F_c = mr_v \omega^2 + \cos \phi mr_d \Omega^2.$$  \hspace{1cm} (9)

The milling ball detaches from the vial wall since $F_c \leq 0$, i.e., the take-off rotation angle $\phi_1$ satisfies

$$\cos \phi_1 = \frac{r_v(\Omega - \omega)^2}{r_d \Omega^2}.$$  \hspace{1cm} (10)

The time required during the movement from the position $P_0(x_0, y_0)$ to $P_1(x_1, y_1)$ can be expressed as

$$t_1 = \frac{\phi_1}{\omega}.$$  \hspace{1cm} (11)

The take-off speed ($v$) of the milling ball at the position $P_1(x_1, y_1)$ reads

$$v = \sqrt{\Omega^2 r_d^2 + (\Omega - \omega)^2 r_v^2 + 2\Omega(\Omega - \omega)r_v r_d \cos \phi_1}.$$  \hspace{1cm} (12)

The position vectors for take-off and collision points $P_1(x_1, y_1)$ and $P_2(x_2, y_2)$ are relevant, i.e.,

$$x_2 = x_1 + v_x t_2,$$

$$y_2 = y_1 + v_y t_2.$$  \hspace{1cm} (13)

The milling ball moves in a straight line, and $P_2(x_2, y_2)$ is given by

$$v_x = \frac{dx}{dt} = \frac{v_x}{t_2},$$  \hspace{1cm} (14)

$$v_y = \frac{dy}{dt} = \frac{v_y}{t_2}. $$  \hspace{1cm} (15)

Equation (13) can be changed into a nonlinear equation with an unknown parameter $t_2$, i.e.,

$$v_x^2 t_2^2 + 2(x_1 v_x + y_1 v_y) t_2 - 2\left[x_1 r_d \cos(\phi_1 + \Omega t_2) + y_1 r_d \sin(\phi_1 + \Omega t_2)\right]$$

$$- 2t_2 \left[v_x r_d \cos(\phi_1 + \Omega t_2) + v_y r_d \sin(\phi_1 + \Omega t_2)\right]$$

$$+ 2(x_1 x_c_1 + y_1 y_c_1) = 0.$$  \hspace{1cm} (16)

The angle between the take-off velocity ($v$) at the point $P_2(x_2, y_2)$ and the radial direction of the vial can be described as

$$\varphi = \beta - \alpha.$$  \hspace{1cm} (17)

where $\beta$ is the angle between the radius $C_2P_2$ and the horizontal line, i.e., $\beta = \tan^{-1}\left((y_2 - y_c_2)/(x_2 - x_c_2)\right)$; $\alpha$ is the angle between the velocity $v$ and the horizontal line, i.e., $\alpha = \tan^{-1}(v_y/v_x)$. Substituting the above formulae into Eq. (17), we have

$$\varphi = \tan^{-1}\left(\frac{y_2 - y_c_2}{x_2 - x_c_2}\right) - \tan^{-1}\left(\frac{v_y}{v_x}\right).$$  \hspace{1cm} (18)

A dynamic cycle of the milling ball starts from the moment when it detaches from the vial wall. After a certain time of movement $t_2$, the milling ball adheres to the vial wall for a certain time $t_1$. Then, the ball detaches from the vial wall and enters into the next...
operation cycle. The total time for a complete cycle of ball motion can be computed according to

$$t_{\text{cycle}} = t_1 + t_2,$$

where

$$t_1 = \frac{1}{f_1}$$

and

$$t_2 = \frac{1}{f_2}.$$

The frequency of ball motion is

$$f = \frac{1}{t_{\text{cycle}}}.$$  \hspace{1cm} (20)

The impact kinetic energy of the milling ball can be calculated by

$$E_t = 0.5m_0v_r^2,$$  \hspace{1cm} (21)

where $v_r$ is the relative velocity of the milling ball to the vial, which can be calculated by

$$v_r = \left| v_{\text{pi}} - v_{\text{flight}} \right|, \hspace{1cm} (22)$$

where $v_{\text{pi}}$ is the velocity vector of the vial at the position $P_2 (x_2, y_2)$, and $v_{\text{flight}}$ is the velocity vector of the milling ball at position $P_2 (x_2, y_2)$.

The impact power of the milling ball is given as follows:[9]

$$P_t = fE_t.$$  \hspace{1cm} (23)

### 3. A model for the local energy transfer during the ball milling process

In the model illustrated in Ref. [1], collision may occur over a range of impact angles, and this geometrical feature might have an important effect on the relative tendencies for coalescence and fragmentation of the powder. For example, several types of fracture can occur, depending on the impact angle, normal collision, shear friction, etc. The powder particles trapped between the colliding balls undergo severe plastic deformation, which flattens them. Under the cumulative effect of ball milling, the powder particles distributing evenly on the surface of ball become finer, leading to new surface areas.

During collision, various kinds of forces can be classified into normal collision force ($F_n$) and shear force ($F_t$), as shown in Fig. 4. The Hertzian impact theory applies, if the kinetic energy dissipation associated with the relative motion of the colliding bodies is much less than the elastic energy content of the bodies. In the model, the relative velocity of the milling balls is much less than the speed of sound in the material, which meets the above requirement.[18,19] We reach the following conclusions: the collisions are perfectly elastic, without energy loss; gradual compression of the milling balls is assumed, where kinetic energy is gradually transformed into stored elastic energy; since the Hertz radius ($r_h$) is much smaller than the radius of the milling ball, the milling surface of the collision can be assumed to be flat, as shown in Fig. 4.[1,18]

![Fig. 4. The contact surface of the collision of milling balls.](https://example.com/f4.png)

The impact forces acting on the milling ball can be computed according to the following formulae:[1]

$$\tau = g_r v_n^{0.2} (\rho_B / \rho_{\text{eff}})^{0.4} r_b,$$  \hspace{1cm} (24)

$$\rho_h = g_r v_n^{0.4} (\rho_B / \rho_{\text{eff}})^{0.2} r_b,$$  \hspace{1cm} (25)

$$\delta_{\text{max}} = r_h^2 / 2r_b,$$  \hspace{1cm} (26)

$$P_n = g_r v_n^{0.4} (\rho_B / \rho_{\text{eff}})^{0.2} E_{\text{eff}},$$  \hspace{1cm} (27)

$$h_0 = \left[ 16(L - 2r_b) / \rho_B / \rho_{\text{eff}} C_R \right] \times \left[ n_B r_h^2 / (3L D_m^2 - 16n_B r_h^2) \right].$$  \hspace{1cm} (28)

where $g_r$, $g_t$, and $g_\theta$ are coefficients depending on the collision geometry. Their values are given in Table 1 for some common MC configurations. The $v_n$ is the normal impact velocity of milling balls, $\rho$ is the density of milling balls, $E_{\text{eff}}$ is the effective flexibility modulus of collision media, $r_h$ is the radius of milling balls, $D_m$
is the diameter of the vial, \( L \) is the height inside the vial, \( n_B \) is the number of milling balls, \( \rho_B \) and \( \rho_p \) are the densities of milling balls and powder, respectively, and \( C_R \) is the ratio of milling ball mass and the power mass.

The normal impact force \( F_n \) can be given by

\[
F_n = P_n \pi r_b^2.
\] (29)

The shear force \( (F_t) \) is a function of the tangential component \( (v_t) \) of the relative collision velocity \( (v_r) \) of milling balls and the rotation velocity \( (v_y) \), where \( v_b = \omega r_b \), and \( \omega \) is the rotation angular velocity. Its expression is given by

\[
F_t = m \frac{d}{dt}(v_t + \omega r_b).
\] (30)

Position \( P_2(x_2, y_2) \) obeys the law of conservation of momentum, i.e.,

\[
\frac{d}{dt}[m v_t r_b + m(r_b^2 + r_y^2)\omega_t] = 0.
\] (31)

Thus, \( \omega_t \) can be removed by integrating Eqs. (30) and (31)

\[
F_t = -\frac{m}{(1 + r_b^2/r_y^2)} \left( \frac{dv_t}{dt} \right)
\] (32)

Given that the velocity of the milling ball is reduced from \( v_t \) to zero in an interval of \( \tau/2 \), by integrating Eq. (32) we have

\[
\int_0^{\tau/2} dt = -F_t \int_0^{v_t} \frac{m}{(1 + r_b^2/r_y^2)} \int_0^\tau dv.
\] (33)

Thus, the expression of shear impact force \( F_t \) can be obtained

\[
F_t = m \frac{2v_t}{(1 + r_b^2/r_y^2) \tau}.
\] (34)

The elastic energy for deformation per unit volume equals \( P_n^2/2E_{eff} \), and the volume deformation caused by collision equals \( 2\pi r_b^2 \delta_{max}/3 \). Thus, the elastic impact energy \( E_e \) and the effective power \( P_e \) per impact can be expressed as

\[
E_e = \frac{\pi P_n^2r_b^2 \delta_{max}}{6E_{eff}},
\] (35)

\[
P_e = f E_e.
\] (36)

The equation of the effective power found here will be applied to identify the optimum milling condition through mathematics, rather than experiments.

4. Applications of the trajectory and energy models

4.1. Simulation of the effect of disk rotation velocity on kinetic parameters

For commercial planetary ball mills, the rotation velocity of the disk \( \Omega \) and vial \( \omega \) are generally in a fixed ratio. In this simulation, the variation of the ratio \( \omega/\Omega \) ranges from 1.0 to 2.0, covering all applications of conventional milling balls, e.g. Kexi (Nanjing), Fritsch, Retsch et al., while the rotation velocity of the disk \( \Omega \) ranges from 200 to 900 rpm.

The setup operating parameters and interrelated physical parameters are shown in Table 2. Figure 5 represents the variations of the frequency of collision \( f \), the total kinetic energy of milling ball \( E_t \) and the collision power \( P_t \) as a function of \( \Omega \); those are obtained from Eqs. (1)–(23) established in the kinetic model for the trajectory of a single milling ball.

As shown in Fig. 5, the values of \( f \), \( E_t \), and \( P_t \) increase monotonically with \( \Omega \). Specifically, \( f \) increases linearly, while \( E_t \) and \( P_t \) show a parabolic increase, which is similar to that reported by Abdellaoui et al.\[^9\] and Chattopadhyay et al.\[^13\] The variation tendencies of \( P_t \) and \( E_t \) are similar to that of the ratio \( \omega/\Omega \). That is to say, the values of \( P_t \) and \( E_t \) manifest a monotonic increase with the ratio \( \omega/\Omega \). This is because that for a given \( \Omega \), the increase of the rotation velocity of the vial enhances the energy input to the milling ball. However, the frequency of collision \( f \) approaches its plateau and bottom at \( \omega/\Omega = 1.25 \) and 2.

respectively, for a given level of $\Omega$. Since the variations of the angle of incidence and the distance of movement resulted from the ratio $\omega/\Omega$ leads to the variation of $f$.

Fig. 5. (colour online) Variations of (a) the collision power $P_t$, (b) the collision frequency $f$, (c) the total kinetic energy $E_t$ as functions of the rotation velocity of the planetary disk $\Omega$ for different levels of the vial-to-disk speed ratio $\omega/\Omega$.

The present simulation has confirmed\cite{13} that the level of $f$ is determined by both $\omega$ and $\Omega$, but the limiting value of $f$ is determined by the ratio $\omega/\Omega$. There is a difference in the variation of $P_t$ with $\omega$ between the report of Chattopadhyay et al.\cite{13} and the present simulation result: $P_t$ depends on $\omega$ evidently rather than $E_t$ in the former research; while in the latter one, both $P_t$ and $E_t$ manifest a small increase with $\omega$, which may be due to that the ratio $\omega/\Omega > 1$.

Figure 6 represents the variations of the normal impact force $F_n$, the shearing force $F_t$, and the normal pressure $P_n$ as functions of $\Omega$, which are obtained from Eqs. (24)–(36) established in the model for the local energy transfer during the ball milling process and the defined collision relative velocity $v_r$ and angular $\varphi$.

As shown in Fig. 6, $F_n$, $F_t$, and $P_n$ manifest a monotonic increase with $\Omega$. The values of $F_n$ and $P_n$ gradually decrease while $F_t$ increases with the increase of ratio $\omega/\Omega$ for a given level of $\Omega$, since the collision angular $\varphi$ exhibits a gradual increase with the ratio $\omega/\Omega$. The results obtained are in good agreement with that obtained by Chattopadhyay et al.\cite{13}

4.2. Simulation of the influence of ratio $\omega/\Omega$ on kinetic parameters

It has been proved that the milling ball becomes adherent to the vial wall, without rolling or sliding on the inner wall, when the value of $\omega/\Omega$ is either less than 0.7 or greater than 3.17. Consequently, we focus
on the variation of $\omega/\Omega$ in a range from 0.7 to 3.17. In addition, the rotation velocity of the disk ranges from 200 to 900 rpm, and the values of other relevant parameter are summarized in Table 3.

As shown in Fig. 7, the velocity of collision $v_r$ manifests a gradual increase with both $\Omega$ and $\omega/\Omega$, which is consistent with the variations of $E_t$ and $P_t$, as reported in Section 3.1. As the ratio $\omega/\Omega$ increases, the angle between impact direction and vial wall gradually declines from 90° to 0° at $\omega/\Omega = 2.17$, increases gradually until becoming perpendicular to the vial wall, then declines again until tangentially adherent to the vial wall. When $\omega/\Omega > 3.179$, the milling ball no longer detaches from the vial wall to move into the vial, since the centrifugal force originating from the rotation of the vial is much greater than that of the disk. Thus, the angle of collision depends primarily on $\omega/\Omega$. The kinetic trajectory of a milling ball is defined for a given ratio $\omega/\Omega$; while the collision velocity is determined by $\Omega$ and $\omega/\Omega$.

As shown in Fig. 7, the velocity of collision $v_r$ manifests a gradual increase with both $\Omega$ and $\omega/\Omega$, which is consistent with the variations of $E_t$ and $P_t$, as reported in Section 3.1. As the ratio $\omega/\Omega$ increases, the angle between impact direction and vial wall gradually declines from 90° to 0° at $\omega/\Omega = 2.17$, increases gradually until becoming perpendicular to the vial wall, then declines again until tangentially adherent to the vial wall. When $\omega/\Omega > 3.179$, the milling ball no longer detaches from the vial wall to move into the vial, since the centrifugal force originating from the rotation of the vial is much greater than that of the disk. Thus, the angle of collision depends primarily on $\omega/\Omega$. The kinetic trajectory of a milling ball is defined for a given ratio $\omega/\Omega$; while the collision velocity is determined by $\Omega$ and $\omega/\Omega$.

According to the results reported previously, the variations of certain kinetic parameters including $f$, $E_t$, $P_t$, $F_h$, $F_t$, and $P_n$ with $\Omega$ are similar. Thus, the variations of these parameters with $\omega/\Omega$ can be studied for a given $\Omega$.

As shown in Fig. 8, the simulation calculation is carried out at $\Omega = 800$ rpm. The values of $v_r$ and $P_t$ increase monotonically with $\omega/\Omega$. Since the rotation velocity of the vial increases gradually with $\omega/\Omega$, the $v_r$ and $P_t$ increase with the kinetic energy of the system input. While the increasing tendencies of $v_r$ and $P_t$ are different since the frequency of collision increases non-monotonically.

As shown in Fig. 9, the frequency of collision frequency $f$ increases to a peak at $\omega/\Omega = 1.4$, then decreases to its minimal value at $\omega/\Omega = 2.3$, and finally approaches its maximum rapidly. The value of $f$ is determined by the operating cycle $t_{cycle} = t_1 + t_2$. As the ratio $\omega/\Omega$ increases, $t_1$ decreases, and $t_2$ increases to its maximum at $\omega/\Omega = 2.3$, and then decreases to 0, i.e., the ball becomes adherent to the vial wall.

As shown in Fig. 10, the normal impact force $F_n$ decreases gradually to 0 with the increase of $\omega/\Omega$ at $\omega/\Omega = 2.17$, and then increases monotonically to its maximum at $\omega/\Omega = 2.86$, and finally decreases to 0. The shear force $F_t$ increases to a peak at $\omega/\Omega = 1.90$, decreases slightly until $\omega/\Omega = 2.10$, increases to another peak at $\omega/\Omega = 2.40$, decreases to 0 at $\omega/\Omega = 2.86$, and increases afterwards.

The effective power $P_e$ per impact is an important parameter to measure the kinetic energy transferred by the ball, which greatly affect the powder by collision, leading to the mechanochemical reaction. The conversion efficiency $\eta$ reflects the conversion efficiency from total power to effective power: $\eta = P_e / P_t \times 100\%$. As shown in Fig. 11, $P_e$ increases smoothly with $\omega/\Omega$ at first, and reaches its first peak at $\omega/\Omega = 1.15$. Then, it decreases to its minimal value at $\omega/\Omega = 2.17$ and increases to another peak at $\omega/\Omega = 2.86$. Finally, it decreases rapidly. Despite the monotonic increase of the total power with $\omega/\Omega$, there are two peaks of the conversion efficiency $\eta$ which exit close to the two peaks of $P_e$, respectively.

From the theoretical viewpoint, the optimal operating condition should be chosen at $\omega/\Omega = 1.15$ or 2.86 in order to obtain the highest impact energy. However, since the rotation velocities of the disk and vial are generally in a fixed ratio for commercially-applied planetary ball mills, the ratio $\omega/\Omega$ is required to be below 2. Conventional ball mills, e.g. Fritsch P5 and Retsch P7, have $\omega/\Omega = 1.25$ and $\omega/\Omega = 1$, respectively, thus to obtain high impact energy.

5. Conclusions

The trajectory and energy models presented here illustrate the relationships between the kinetic and dynamic parameters. The effects of the rotation velocity of the disk $\Omega$ and the vial-to-disk speed ratio $\omega/\Omega$ on other kinetic parameters have been studied. All other kinetic parameters increase monotonously with the increase of the rotation velocity $\Omega$. With the variation of the ratio $\omega/\Omega$, the impact angle of the milling ball $\phi$ ranges from 90° to 0°. Thus, the ideal values of the normal impact force $F_n$ and tangential force $F_t$ can be obtained. When the dynamic parameters of the planetary ball mill are given, the highest impact energy $P_e$ can be obtained for the optimal value of $\omega/\Omega$. The optimal ratio $\omega/\Omega$ is found to be 1.15 at $\Omega = 800$ rpm.

The established models can improved by taking account of the slip factor. Nevertheless, this work verifies the practical consistency of the models, and provides a governing principle to predict an optimal milling condition. The application of the models can predict the parameters needed to obtain a certain and optimal milling condition with higher milling efficiency.
